Pharmacodynamic interaction: Drugs that may reduce the blood glucose-lowering effect of insulins can increase the risk of hypoglycemia.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
None.

**Clinical consequences:**
May require insulin dose adjustment and particularly close monitoring.

**Reference:**
Apidra prescribing information, Humulin prescribing information, Humalog prescribing information, Lantus prescribing information, Novolog prescribing information.

---

**Drug-Drug Interaction Monograph for ARCALYST (Rilonacept) #1**

---

**Perpetrator drug:**
INN name/US brand name: TNF-blocking agents
Class/Molecular weight:
**Victim drug:**
INN name/US brand name: Rilonacept/Arcalyst
Class/Molecular weight: Fusion protein/251 kDa

**Description of the effect of the DDI:**
Pharmacodynamic interaction: Concomitant administration of another drug that blocks IL-1 with a TNF-blocking agent in another patient population has been associated with an increased risk of serious infections and an increased risk of neutropenia. Concomitant administration of rilonacept with TNF-blocking agents may also result in similar toxicities and is not recommended.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Both are immunomodulators which carry the risk of increased infections.

**Clinical consequences:**
Increased risk of serious infections and neutropenia.

**Reference:**
Arcalyst prescribing information.

---

**Drug-Drug Interaction Monograph for ARCALYST (Rilonacept) #2**

---

**Perpetrator drug:**
INN name/US brand name: Rilonacept/Arcalyst
Class/Molecular weight: Fusion protein/251 kDa

**Victim drug:**
INN name/US brand name: CYP450 substrates
Class/Molecular weight:

**Description of the effect of the DDI:**
Normalization of CYP450 enzymes.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
The formation of CYP450 enzymes is suppressed by increased levels of cytokines (e.g., IL-1) during chronic inflammation. Thus it is expected that for a molecule that binds to IL-1, such as rilonacept, the formation of CYP450 enzymes could be normalized.

**Clinical consequences:**
Clinically relevant for CYP450 substrates with narrow therapeutic index. Upon initiation of rilonacept, in patients being treated with these types of medicinal products, therapeutic monitoring of the effect or drug concentration should be performed and the individual dose of the medicinal product may need to be adjusted as needed.

| INN name/US brand name: | Anticholinergic drugs |
| Class/Molecular weight: | |

**Description of the effect of the DDI:**
<Note: Besides cosmetic uses, Onabotulinumtoxin A is also used for the treatment of destusor overactivity associated with a neurologic condition, chronic migraine, upper limb spasticity, cervical dystonia, primary axillary hyperhidrosis, blepharospasm and strabismus>

Use of anticholinergic drugs after administration of Botox may potentiate systemic anticholinergic effects.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
None.

**Clinical consequences:**
None.

**Reference:**
Botox prescribing information.

Dysport prescribing information.

**Drug-Drug Interaction Monograph for BOTOX, DYSPORT (Onabotulinumtoxin) #3**

**Perpetrator drug:**
INN name/US brand name: Muscle relaxants
Class/Molecular weight:

**Victim drug:**
INN name/US brand name: Onabotulinumtoxin A/Botox, Dysport
Class/Molecular weight: Protein Toxin/149.3 kDa

**Description of the effect of the DDI:**
<Note: Besides cosmetic uses, Botox is also used for the treatment of destusor overactivity associated with a neurologic condition, chronic migraine, upper limb spasticity, cervical dystonia, primary axillary hyperhidrosis, blepharospasm and strabismus>

Excessive weakness may be exaggerated by administration of a muscle relaxant before or after administration of onabotulinumtoxin A.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
None.

**Clinical consequences:**
None.

**Reference:**
Botox prescribing information.

Dysport prescribing information.

**Drug-Drug Interaction Monograph for BYDUREON (Exenatide) #1**

**Perpetrator drug:**
INN name/US brand name: Orally administered drugs
Class/Molecular weight:

**Victim drug:**
INN name/US brand name: Exenatide/Bydureon
Class/Molecular weight: Peptide/4.2 kDa

**Description of the effect of the DDI:**
Exenatide has the potential to reduce the extent and rate of absorption of orally administered drugs.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Exenatide slows gastric emptying.

**Clinical consequences:**
Use caution when administering oral medications with exenatide. Exenatide should be used with caution in patients receiving oral medications that have narrow therapeutic index or require rapid gastrointestinal absorption. For oral medications that are dependent on threshold concentrations for efficacy, such as contraceptives and antibiotics, patients should be advised to take those drugs at least 1 hour before exenatide injection. If such drugs are to

*(Continued)*

be administered with food, patients should be advised to take them with a meal or snack when exenatide is not administered

**Reference:**
Bydureon prescribing information.

Byetta prescribing information.

---

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Acetaminophen/Tylenol |
| Class/Molecular weight: | Small molecule/151 Da |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Exenatide/Bydureon |
| Class/Molecular weight: | Peptide/4.2 kDa |

**Description of the effect of the DDI:**
In patients with type 2 diabetes, exenatide did not affect the absorption of orally administered acetaminophen to any clinically relevant degree.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
No DDI.

**Clinical consequences:**
None.

**Reference:**
Bydureon prescribing information.

(not in Byetta labeling)

---

**Drug-Drug Interaction Monograph for BYDUREON (Exenatide) #3**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Warfarin/Coumadin |
| Class/Molecular weight: | Small molecule/308 Da |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Exenatide/Bydureon, Byetta |
| Class/Molecular weight: | Peptide/4.2 kDa |

**Description of the effect of the DDI:**
There are postmarketing reports of increased INR with concomitant use of warfarin, sometimes associated with bleeding. In a drug interaction study, exenatide did not have a significant effect on INR.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
None.

**Clinical consequences:**
In patients taking warfarin, the INR should be monitored more frequently after initiating BYDUREON. Once a stable INR has been documented, the INR can be monitored at the intervals usually recommended for patients on warfarin.

**Reference:**
Bydureon prescribing information.

Byetta prescribing information.

---

**Drug-Drug Interaction Monograph for CIMZIA (Certolizumab)**

---

**Perpetrator drug:**
INN name/US brand name: TNF-blocking agents and other immune modulators (e.g. anakinra, abatacept, rituximab, and natalizumab)
Class/Molecular weight:

**Victim drug:**
INN name/US brand name: Certolizumab pegol /Cimzia
Class/Molecular weight: Antibody Fab' fragment/91 kDa

**Description of the effect of the DDI:**
An increased risk of serious infections has been seen in clinical studies of other TNF-blocking agents used in combination with anakinra or abatacept, with no added benefit. Formal drug interaction studies have not been performed with rituximab or natalizumab. Because of the nature of the adverse events seen with these combinations with TNF blocker therapy, similar toxicities may also result from the use of Cimzia in these combinations.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Immunomodulatory effects of both agents.

**Clinical consequences:**
There is not enough information to assess the safety and efficacy of such combination therapy. Therefore, the use of certolizumab pegol in combination with anakinra, abatacept, rituximab, or natalizumab is not recommended

**Reference:**
Cimzia prescribing information.

De Stefano N, Filippi M, Hawkins C. Short-term combination of glatiramer acetate with i.v. steroid treatment preceding treatment with GA alone assessed by MRI-disease activity in patients with relapsing-remitting multiple sclerosis. J Neurol Sci. 2008;266(1–2):44–50.

Copaxone prescribing information.

## Drug-Drug Interaction Monograph for CUBICIN (Daptomycin)

**Perpetrator drug:**

INN name/US brand name: Daptomycin/Cubicin
Class/Molecular weight: Cyclic lipopeptide/1.6 kDa

**Victim drug:**

INN name/US brand name: Simvastatin/Zocor
Class/Molecular weight: Small molecule/419 Da

**Description of the effect of the DDI:**

In healthy subjects, concomitant administration of daptomycin and simvastatin had no effect on plasma trough concentrations of simvastatin, and there were no reports of skeletal myopathy.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**

None.

**Clinical consequences:**

Experience with the coadministration of HMG-CoA reductase inhibitors and daptomycin in patients is limited; therefore, consideration should be given to suspending use of HMG-CoA reductase inhibitors temporarily in patients receiving daptomycin.

**Reference:**

Cubicin prescribing information.

**Drug-Drug Interaction Monograph for DDAVP (Desmopressin) #1**

**Perpetrator drug:**
INN name/US brand name: Pressor Agents
Class/Molecular weight:

**Victim drug:**
INN name/US brand name: Desmopressin/DDAVP
Class/Molecular weight: Peptide/1.2 kDa

**Description of the effect of the DDI:**
Desmopressin generally has very low pressor activity compared to the antidiuretic activity. However large doses of desmopressin with other pressor agents could potentiate the pressor effect.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Pharmacodynamic synergy.

**Clinical consequences:**
Although the pressor activity of desmopressin is very low compared to the antidiuretic activity, use of large doses of intranasal mesmopressin with other pressor agents should only be done with careful patient monitoring.

**Reference:**
DDAVP prescribing information.

**Drug-Drug Interaction Monograph for DDAVP (Desmopressin) #2**

**Perpetrator drug:**
INN name/US brand name: Drugs that may cause hyponatremia (e.g. tricyclic antidepressants, selective serotonin re-uptake inhibitors, chlorpromazine, opiate analgesics, NSAIDs, lamotrigine and carbamazepine)
Class/Molecular weight:

**Victim drug:**
INN name/US brand name: Desmopressin/DDAVP
Class/Molecular weight: Peptide/1.2 kDa

**Description of the effect of the DDI:**
Increased risk of hyponatremia. Several cases of mild to moderate hyponatremia have been reported as well as a severe case of hyponatremia after administration of desmopressin.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Pharmacodynamic synergy. Desmopressin is an synthetic analog of vasopressin and stimulates collecting duct aquaporin expression and subsequent resorption of water to the renal parenchyma.

*(Continued)*

**Clinical consequences:**
The concomitant administration of drugs that may increase the risk of water intoxication with hyponatremia, (e.g. tricyclic antidepressants, selective serotonin re-uptake inhibitors, chlorpromazine, opiate analgesics, NSAIDs, lamotrigine and carbamazepine) should be performed with caution.

**Reference:**
Kelleher HB, Henderson SO. Severe hyponatremia due to desmopressin. J Emerg Med. 2006;30(1):45–7.

DDAVP prescribing information.

---

**Drug-Drug Interaction Monograph for ERBITUX (Cetuximab)**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Cetuximab/Erbitux |
| Class/Molecular weight: | Monoclonal Antibody/152 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Irinotecan/Camptosar |
| Class/Molecular weight: | Small Molecule/677.2 Da |

**Description of the effect of the DDI:**
There was no evidence of any pharmacokinetic interactions between cetuximab and irinotecan.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Not applicable.

**Clinical consequences:**
No dose adjustment is needed.

**Reference:**
Delbaldo C et al (2005). Pharmacokinetic profile of cetuximab (Erbitux) alone and in combination with irinotecan in patients with advanced EGFR-positive adenocarcinoma. Eur J Cancer 41(12):1739–1745.

---

**Drug-Drug Interaction Monograph for ENBREL (Etanercept) #1**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Abatacept/Orencia |
| Class/Molecular weight: | Fusion Protein/92 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Etanercept/Enbrel |
| Class/Molecular weight: | Fusion Protein/150 kDa |

**Description of the effect of the DDI:**
The incidence of total serious adverse events in the combination therapy of abatacept and background biologic treatment (64.1% etanercept) was much higher (23%) than that (8%) of background biologic treatment (65.6% etanercept).

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Mechanism is not known.

**Clinical consequences:**
Use of etanercept with abatacept is not recommended.

**Reference:**
Enbrel prescribing information

Weinblatt M et al (2006). Safety of the selective costimulation modulator abatacept in rheumatoid arthritis patients receiving background biologic and nonbiologic disease-modifying antirheumatic drugs: A one-year randomized, placebo-controlled study. Arthritis Rheumatism 54(9): 2807–2816.

---

**Drug-Drug Interaction Monograph for ENBREL (Etanercept) #2**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Anakinra/Kineret |
| Class/Molecular weight: | IL-1 Receptor Antagonist/17.3 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Etanercept/Enbrel |
| Class/Molecular weight: | Fusion Protein/150 kDa |

**Description of the effect of the DDI:**
In a study in which patients with active rheumatoid arthritis were treated for up to 24 weeks with concurrent etanercept and anakinra therapy, a 7% rate of serious infections was observed, which was higher than that observed with etanercept alone (0%). Two percent of patients treated concurrently with etanercept and anakinra developed neutropenia (ANC $< 1 \times 109$/L).

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Mechanism is not known.

**Clinical consequences:**
Use of etanercept with anakinra is not recommended.

**Reference:**
Enbrel prescribing information.

Genovese MC et al (2004). Combination therapy with etanercept and anakinra in the treatment of patients with rheumatoid arthritis who have been treated unsuccessfully with methotrexate. Arthritis Rheumatism 50(5): 1412–1419.

---

**Drug-Drug Interaction Monograph for ENBREL (Etanercept) #3**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Etanercept/Enbrel |
| Class/Molecular weight: | Fusion Protein/150 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Digoxin/Lanoxin |
| Class/Molecular weight: | Small Molecule/780.95 Da |

*(Continued)*

**Description of the effect of the DDI:**
Digoxin maximum plasma concentration ($C_{max}$) and area under the plasma concentration versus time curve(AUC) were not altered by the coadministration of etanercept. The mean Cmax and AUC of etanercept were 4.2% and 12.5% lower, respectively, when etanercept was given with digoxin than when administered alone. There were no clinically relevant changes in the electrocardiogram (ECG) parameters when both drugs were combined.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Not applicable.

**Clinical consequences:**
There is no clinically relevant interaction between etanercept and digoxin, and both drugs can be safely coadministered without the need for a dosage adjustment.

**Reference:**
Zhou H et al (2004). Absence of a clinically relevant interaction between etanercept and digoxin. J Clin Pharmacol 44: 1244–1251.

---

**Drug-Drug Interaction Monograph for ENBREL (Etanercept) #4**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Etanercept/Enbrel |
| Class/Molecular weight: | Fusion Protein/150 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Pneumococcal Polysaccharide Vaccine/Pneumovax |
| Class/Molecular weight: | Vaccine/NA |

**Description of the effect of the DDI:**
Most patients with psoriatic arthritis receiving etanercept were able to mount effective B-cell immune responses to pneumococcal polysaccharide vaccine, but titers in aggregate were moderately lower and fewer patients had 2-fold rises in titers compared to patients not receiving Enbrel.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Mechanism is not known.

**Clinical consequences:**
The clinical relevance is unknown.

**Reference:**
Enbrel prescribing information.

---

**Drug-Drug Interaction Monograph for ENBREL (Etanercept) #5**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Etanercept/Enbrel |
| Class/Molecular weight: | Fusion Protein/150 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Warfarin/Coumadin, Jantoven, Marevan, Lawarin, etc. |
| Class/Molecular weight: | Small Molecule/330.3 Da |

**Description of the effect of the DDI:**
Etanercept did not affect the pharmacokinetics and pharmacodynamics of warfarin. All ratios of maximum serum concentration ($C_{max}$) and area under the serum concentration versus time curve (AUC) for pharmacokinetics (R- and S-enantiomers of warfarin) and International Normalized Ratio (INR) fell within the confidence interval of 0.8 to 1.25.

Warfarin also did not cause a clinically significant alteration in the pharmacokinetics of etanercept.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Not applicable.

**Clinical consequences:**
Coadministration of etanercept and warfarin would not be expected to change the pharmacokinetics of either medication; therefore, no dosage adjustment is needed in cases in which warfarin and etanercept are coadministered.

**Reference:** Zhou H et al (2004). Absence of a pharmacokinetic interaction between etanercept and warfarin. J Clin Pharmacol 44: 543–550.

---

**Drug-Drug Interaction Monograph for ENBREL (Etanercept) #6**

**Perpetrator drug:**
INN name/US brand name: Methotrexate/Mexate, Folex, Rheumatrex
Class/Molecular weight: Small Molecule/454.5 Da

**Victim drug:**
INN name/US brand name: Etanercept/Enbrel
Class/Molecular weight: Fusion Protein/150 kDa

**Description of the effect of the DDI:**
Based on the bioequivalence criteria, the Bayesian-estimated clearance for patients receiving etanercept alone (mean: 0.070 L/h) was comparable to that for patients receiving a combination of etanercept and methotrexate (mean = 0.066 L/h). The pharmacokinetics of etanercept were not altered by the concurrent administration of methotrexate in patients with rheumatoid arthritis.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Not applicable.

**Clinical consequences:**
No etanercept dose adjustment is needed for patients taking concurrent methotrexate.

**Reference:**
Zhou H et al (2004). Unaltered etanercept pharmacokinetics with concurrent methotrexate in patients with rheumatoid arthritis. J Clin Pharmacol 44: 1235–1243.

---

**Drug-Drug Interaction Monograph for EXUBERA (Insulin human)**

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Albuterol/Ventolin, Proventil, Proventil-HFA, AccuNeb, Vospire, ProAir |
| Class/Molecular weight: | Small Molecule/576.7 Da |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Insulin Human/Exubera |
| Class/Molecular weight: | Peptide Hormone/5.8 kDa |

**Description of the effect of the DDI:**
Administration of albuterol 30 minutes prior to administration of insulin in non-diabetic subjects with both mild asthma (n = 36) and moderate asthma (n = 31) resulted in a mean increase in insulin AUC and Cmax of between 25 and 50% compared to when insulin was administered alone.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
The mechanism is not known. Albuterol, a short-acting beta-agonist that works as a bronchodilator, may enhance insulin's inhalation/absorption through its bronchodilatory effect.

**Clinical consequences:**
Consistent timing of dosing of bronchodilators relative to insulin administration, close monitoring of blood glucose concentrations and dose titration as appropriate are recommended.

**Reference:**
http://www.accessdata.fda.gov/drugsatfda_docs/nda/2006/021868s000_ClinPharmR.pdf.
http://www.accessdata.fda.gov/drugsatfda_docs/label/2008/021868s016s017lbl.pdf.

**Drug-Drug Interaction Monograph for HUMIRA (Adalimumab) #1**

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Adalimumab/Humira |
| Class/Molecular weight: | Monoclonal Antibody/148 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Methotrexate/Rheumatrex, Trexall |
| Class/Molecular weight: | Small Molecule/454.5 Da |

**Description of the effect of the DDI:**
Repeated administration of adalimumab had no statistically significant effect on the pharmacokinetics of methotrexate.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
None.

**Clinical consequences:**
No dose adjustment is needed.

**Reference:** Weisman M et al. Efficacy, pharmacokinetic, and safety assessment of adalimumab, a fully human anti-tumor necrosis factor-alpha monoclonal antibody, in adults with rheumatoid arthritis receiving concomitant methotrexate: a pilot study. Clin Therapeutics 2003;25(6):1700–1721.

---

**Drug-Drug Interaction Monograph for HUMIRA (Adalimumab) #2**

---

**Perpetrator drug:**

INN name/US brand name: Methotrexate/Rheumatrex, Trexall
Class/Molecular weight: Small Molecule/454.5 Da

**Victim drug:**

INN name/US brand name: Adalimumab/Humira
Class/Molecular weight: Monoclonal Antibody/148 kDa

**Description of the effect of the DDI:**
Methotrexate reduced adalimumab apparent clearance after single and multiple dosing by 29% and 44%, respectively.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Methotrexate lowers adalimumab's clearance by decreasing the incidence of immunogenicity and/or operating via interacting Fcγ receptor.

**Clinical consequences:**
No dose adjustment is needed.

**Reference:** Humira prescribing information.

---

**Drug-Drug Interaction Monograph for INTRON A (Interferon alfa-2B)**

---

**Perpetrator drug:**

INN name/US brand name: Interferon Alfa-2B/Intron A
Class/Molecular weight: Cytokine/19.3 kDa

**Victim drug:**

INN name/US brand name: Theophylline/Elixophyllin, Theo-24, Theolair, etc.
Class/Molecular weight: Small Molecule/180.2 Da

**Description of the effect of the DDI:**
Concomitant use of alpha interferon and theophylline decreases theophylline clearance, resulting in a significant increase in serum theophylline levels.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Intron A inhibits metabolism of theophylline by CYP1A2.

**Clinical consequences:**
No dose adjustment is needed.

**Reference:**
Intron A prescribing information.

Willimas SJ et al. Inhibition of theophylline metabolism by interferon. Lancet 1987;24; 2(8565):939–41.

---

**Drug-Drug Interaction Monograph for IPRIVASK (Desirudin) #1**

**Perpetrator drug:**
INN name/US brand name: Desirudin Recombinant/Iprivask
Class/Molecular weight: Polypeptide/19.2 kDa

**Victim drug:**
INN name/US brand name: Warfarin/Coumadin, Jantoven, Marevan, Lawarin, etc.
Class/Molecular weight: Small Molecule/330.3 Da

**Description of the effect of the DDI:**
Warfarin (2 × 5 mg daily oral administration) did not significantly affect the pharmacokinetics of desirudin.

There was an additive effect of desirudin on activated partial thromboplastin time (aPTT), prothrombin time (PT), and international normalized ratio (INR) when co-administered with warfarin.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
The exact mechanism is not yet understood.

**Clinical consequences:**
If a patient is switched from oral anticoagulants to desirudin therapy or from desirudin to oral anticoagulants, the anticoagulant activity should continue to be closely monitored with appropriate methods. That activity should be taken into account in the evaluation of the overall coagulation status of the patient during the switch.

**Reference:**
Iprivask prescribing information.

http://www.accessdata.fda.gov/drugsatfda_docs/nda/2003/21-271_Iprivask_BioPharmr.pdf.

**Drug-Drug Interaction Monograph for IPRIVASK (Desirudin) #2**

**Perpetrator drug:**
INN name/US brand name: Acetylsalicylic acid/Aspirin
Class/Molecular weight: Small Molecule/180.1 Da

**Victim drug:**
INN name/US brand name: Desirudin Recombinant/Iprivask
Class/Molecular weight: Polypeptide/19.2 kDa

**Description of the effect of the DDI:**
Acetylsalicylic acid (ASA) had no effect on the pharmacokinetics of desirudin. Administration of ASA had no effect on aPTT and PT produced by intravenous infusion of desirudin. Prolonged bleeding times observed in some patients.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
The exact mechanism is not yet understood.

**Clinical consequences:**
Desirudin should be used with caution in conjunction with drugs which affect platelet function. These medications include systemic salicylates, NSAIDS including ketorolac,

acetylsalicylic acid, ticlopidine, dipyridamole, sulfinpyrazone, clopidogrel, abciximab and other glycoprotein IIb/IIIa antagonists.

**Reference:**
Iprivask prescribing information.

http://www.accessdata.fda.gov/drugsatfda_docs/nda/2003/21-271_Iprivask_BioPharmr.pdf.

---

**Drug-Drug Interaction Monograph for IPRIVASK (Desirudin) #3**

---

**Perpetrator drug:**
INN name/US brand name: Piroxicam/Feldene
Class/Molecular weight: Small Molecule/331.35 Da

**Victim drug:**
INN name/US brand name: Desirudin Recombinant/Iprivask
Class/Molecular weight: Polypeptide/19.2 kDa

**Description of the effect of the DDI:**
When desirudin was coadministered with piroxicam (half of the usual daily dose of 20 mg), no significant pharmacokinetic interaction were observed. Neither was there any obvious alteration of the anticoagulant effect of desirudin.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
The exact mechanism is not yet understood.

**Clinical consequences:**
As with other anticoagulants, desirudin should be used with caution in conjunction with drugs which affect platelet function. These medications include systemic salicylates, NSAIDS including ketorolac, acetylsalicylic acid, ticlopidine, dipyridamole, sulfinpyrazone, clopidogrel, abciximab and other glycoprotein IIb/IIIa antagonists

**Reference:**
Iprivask prescribing information.

http://www.accessdata.fda.gov/drugsatfda_docs/nda/2003/21-271_Iprivask_BioPharmr.pdf.

---

**Drug-Drug Interaction Monograph for IPRIVASK (Desirudin) #4**

---

**Perpetrator drug:**
INN name/US brand name: Heparin/Calciparine and Hep-Lock
Class/Molecular weight: Sulfated Glycosaminoglycan/3–30 kDa

**Victim drug:**
INN name/US brand name: Desirudin Recombinant/Iprivask
Class/Molecular weight: Polypeptide/19.2 kDa

**Description of the effect of the DDI:**
The pharmacokinetics of desirudin was not altered by concomitant infusion of heparin (bolus of 5000 units followed by infusion of 1000 units/hour).

*(Continued)*

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
The exact mechanism is not yet understood.

**Clinical consequences:**
During prophylaxis of venous thromboembolism, concomitant treatment with heparins (unfractionated and low-molecular weight heparins) or dextrans is not recommended. The effects of desirudin and unfractionated heparins on prolongation of aPTT are additive.

**Reference:**
Iprivask prescribing information.

http://www.accessdata.fda.gov/drugsatfda_docs/nda/2003/21-271_Iprivask_BioPharmr.pdf.

---

**Drug-Drug Interaction Monograph for IPRIVASK (Desirudin) #5**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Desmopressin/DDAVP, DesmoMelt, Stimate, Minirin |
| Class/Molecular weight: | Peptide/1069.2 Da |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Desirudin Recombinant/Iprivask |
| Class/Molecular weight: | Polypeptide/19.2 kDa |

**Description of the effect of the DDI:**
There was no effect of desmopressin on the pharmacokinetics of desirudin. However, it was shown that an infusion of desmopressin (0.3 μg/kg) can partially reverse the desirudin induced increase in aPTT and can dramatically increase factor VIII:C levels depending on the rate of ongoing desirudin infusion.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
The exact mechanism is not yet understood.

**Clinical consequences:**
The clinical effectiveness of desmopressin in treating bleeding due to desirudin overdose has not been studied.

**Reference:**
Iprivask prescribing information.

http://www.accessdata.fda.gov/drugsatfda_docs/nda/2003/21-271_Iprivask_BioPharmr.pdf.

---

**Drug-Drug Interaction Monograph for KINERET (Anakinra)**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Methotrexate/Mexate, Folex, Rheumatrex |
| Class/Molecular weight: | Small Molecule/454.5 Da |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Anakinra/Kineret |
| Class/Molecular weight: | IL-1 Receptor Antagonist/17.3 kDa |

**Description of the effect of the DDI:**
Toxicologic and toxicokinetic studies in rats did not demonstrate any alterations in the clearance or toxicologic profile of either methotrexate or anakinra when the two agents were administered together.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
The exact mechanism is not yet understood.

**Clinical consequences:**
No dose adjustment is needed.

**Reference:**
Kineret prescribing information.

---

**Drug-Drug Interaction Monograph for LUVERIS (Lutropin alfa)**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Follitropin Alfa/Gonal-f |
| Class/Molecular weight: | Human hormone/22.7 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Lutropin Alfa/Luveris |
| Class/Molecular weight: | Recombinant human hormone/23.4 kDa |

**Description of the effect of the DDI:**
There are no pharmacokinetic interactions between lutropin alfa (150 IU) with follitropin alfa (150 IU) when administered simultaneously.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
The exact mechanism is not yet understood.

**Clinical consequences:**
No dose adjustment is needed.

**Reference:**
Luveris prescribing information.

http://www.accessdata.fda.gov/drugsatfda_docs/nda/2004/021322s000_Luveris_biopharmr.pdf.

---

**Drug-Drug Interaction Monograph for MIACALCIN (Calcitonin)**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Calcitonin-salmon/Miacalcin |
| Class/Molecular weight: | Polypeptide/3455 Da |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Lithium |
| Class/Molecular weight: | Small Molecule |

**Description of the effect of the DDI:**
Concurrent use of calcitonin and lithium may result in decreased lithium concentrations and loss of lithium efficacy. The co-administration of calcitonin and lithium causes a significant decrease in lithium plasma levels, with the average decrease reaching a maximum of 30%.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Increased renal lithium excretion and/or decreased lithium intestinal absorption.

*(Continued)*

**Clinical consequences:**
Lithium levels should be closely monitored in patients receiving calcitonin therapy. Lithium dose adjustments may be necessary.

**Reference:** Miacalcin prescribing information.

Passiu G, et al. Calcitonin decreases lithium plasma levels in man. Preliminary report. Int J Clin Pharm Res 1998; 18:179–181.

Micromedex

---

**Drug-Drug Interaction Monograph for MIRCERA (Methoxy polyethylene glycol-epoetin beta)**

---

**Perpetrator drug:**
INN name/US brand name: Methoxy polyethylene glycol-epoetin beta/Mircera
Class/Molecular weight: Erythropoietin analog/60 kDa

**Victim drug:**
INN name/US brand name: None
Class/Molecular weight:

**Description of the effect of the DDI:**
No drug interactions have been identified.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
None available.

**Clinical consequences:**
None.

**Reference:** Mircera prescribing information

---

**Drug-Drug Interaction Monograph for MYOBLOC (Rimabotulinumtoxin B)**

---

**Perpetrator drug:**
INN name/US brand name: Aminoglycosides/other agents interfering neuromuscular transmission (e.g., curare-like compounds)
Class/Molecular weight: Small molecule

**Victim drug:**
INN name/US brand name: Rimabotulinumtoxin B/Myobloc
Class/Molecular weight: Two chain polypeptide/150 kDa

**Description of the effect of the DDI:**
Caution should be exercised when co-administering rimabotulinumtoxin B and aminoglycosides or other agents interfering with neuromuscular transmission (e.g., curare-like compounds) as the effect of the toxin may be potentiated.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
None available

**Clinical consequences:**
Toxicity of rimabotulinumtoxin B may increase.

**Reference:** Myobloc prescribing information.

---

**Drug-Drug Interaction Monograph for MYOZYME (Alglucosidase alfa)**

**Perpetrator drug:**
INN name/US brand name: Alglucosidase
Class/Molecular weight: Enzyme/110 kDa

**Victim drug:**
INN name/US brand name: None
Class/Molecular weight:

**Description of the effect of the DDI:**
No drug interactions have been identified.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
None available.

**Clinical consequences:**
None.

**Reference:** Myozyme prescribing information.

---

**Drug-Drug Interaction Monograph for NEUMEGA (Oprelvekin)**

**Perpetrator drug:**
INN name/US brand name: Oprelvekin/Neumega
Class/Molecular weight: Recombinant interleukin/19 kDa

**Victim drug:**
Class/Molecular weight: Opioids

**Description of the effect of the DDI:**
Patient on treatment with opioids and oprelvekin developed respiratory depression and sedation suggested from a sedative medication.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Oprelvekin alters renal handling of water and sodium. Morphine and its metabolites are known to undergo renal elimination, and oprelvekin may have interfered with this process.

**Clinical consequences:**
Precaution should be taken while prescribing oprelvekin to patients already on opioid therapy due to possibility of drug interaction.

**Reference:** Moorehead et al. Suspected interaction of oprelvekin (rhIL-11) with a long-acting opioid. Pediatr Blood Cancer. 2008 Dec;51(6):837

---

**Drug-Drug Interaction Monograph for NEUPOGEN (Filgrastim)**

**Perpetrator drug:**
INN name/US brand name: Filgrastim/Neupogen
Class/Molecular weight: Hematopoietic growth factor/18.8 kDa

**Victim drug:**
INN name/US brand name: Oprelvekin/Neumega
Class/Molecular weight: Recombinant interleukin/19 kDa

**Description of the effect of the DDI:**
No change in pharmacokinetic parameters or toxicity has been observed under co-administration of filgrastim and oprelvekin.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
NA

**Clinical consequences:**
No clinical consequences have been observed.

**Reference:** Neupogen prescribing information.

**Drug-Drug Interaction Monograph for NULOJIX (Belatacept) #1**

**Perpetrator drug:**
INN name/US brand name: Belatacept/Nulojix
Class/Molecular weight: FC-CTLA-4 fusion protein/90.6 kDa

**Victim drug:**
INN name/US brand name: Mycophenolic acid (MPA)
Class/Molecular weight: Small molecule/320.3 Da

**Description of the effect of the DDI:**
In a pharmacokinetic study, the plasma concentrations of mycophenolic acid (MPA) was measured in 41 patients who received fixed mycophenolate mofetil (MMF) doses of 500 mg to 1500 mg twice daily with either 5 mg per kg of belatacept or cyclosporine. The mean dose-normalized MPA $C_{max}$ and $AUC_{0\text{-}12}$ were approximately 20% and 40% higher, respectively, with belatacept coadministration than with cyclosporine coadministration.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Belatacept may cause a decrease in CYP450 activity leading to a decrease in systemic clearance of MPA.

**Clinical consequences:**
Clinicians should be aware that there is a potential change of MPA exposure after crossover from cyclosporine to belatacept or from belatacept to cyclosporine in patients concomitantly receiving MMF.

**Reference:** Nulojix prescribing information.

**Drug-Drug Interaction Monograph for NULOJIX (Belatacept) #2**

**Perpetrator drug:**
INN name/US brand name: Belatacept/Nulojix
Class/Molecular weight: FC-CTLA-4 fusion protein/90.6 kDa

**Victim drug:**
INN name/US brand name: CYP450 substrates
Class/Molecular weight:

**Description of the effect of the DDI:**
No formal drug interaction studies have been conducted with belatacept, but biologic therapies that are cytokines or cytokine modulators have been shown to affect the expression and/or functional activities of CYP450 enzymes.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
*In vitro* studies have shown that belatacept inhibits the production of certain cytokines during an alloimmune response.

**Clinical consequences:**
The potential for belatacept to alter the systemic concentrations of drugs that are CYP450 substrates has not been studied; however, in the event that kidney transplant patients receiving belatacept exhibit signs and symptoms of altered efficacy or adverse events associated with co-administered drugs which are known to be metabolized by CYP450, the clinician should be aware of potentially altered CYP450 metabolism of these drugs.

**Reference:** Nulojix prescribing information.

**Drug-Drug Interaction Monograph for OMNITROPE (Somatropin recombinant)**

**See ACCRETROPIN (Somatropin) drug-drug interaction monographs #1–#4**

**Reference:** Omnitrope prescribing information

**Drug-Drug Interaction Monograph for ONCASPAR (Pegaspargase)**

**Perpetrator drug:**
INN name/US brand name: N/A
Class/Molecular weight:

**Victim drug:**
INN name/US brand name: N/A
Class/Molecular weight:

**Description of the effect of the DDI:**
No formal drug interaction studies between pegaspartase and other drugs have been performed, as per drug label.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
No dose adjustments have been recommended.

**Clinical consequences:**
No clinical consequences have been observed.

**Reference:** Oncaspar prescribing information.

**Drug-Drug Interaction Monograph for ORENCIA (Abatacept)**

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Abatacept/Orencia |
| Class/Molecular weight: | CTLA-4/human IgG1 Fc fusion protein<br>Immune Modulator (Antirheumatic)/92 kDa |

**Victim drug:**

| | |
|---|---|
| Class: | TNF antagonists/inhibitors (etanercept, adalimumab, anakinra, infliximab, golimumab) |

**Description of the effect of the DDI:**
Increased risk of serious infection.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Potentiating effect on inhibition of immune reactivity.

**Clinical consequences:**
Concomitant therapy is not recommended.

**Reference:** Micromedex.

**Drug-Drug Interaction Monograph for ORTHOCLONE OKT3 (Muromonab-CD3)**

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Echinacea preparations |
| Class/Molecular weight: | Herbal preparation |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Muromonab-CD3/Orthoclone OKT3 |
| Class/Molecular weight: | Murine IgG2α monoclonal antibody/146 kDa |

**Description of the effect of the DDI:**
Concurrent use of Echinacea preparations and muromonab-CD3 may result in decreased effectiveness of muromonab-CD3.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
The probable mechanism of interaction is stimulation of the immune system by Echinacea, resulting in increased formation of neutralizing anti-drug antibodies.

**Clinical consequences:**
Since reduced muromonab effectiveness may be life threatening in organ transplantation, the concomitant use of Echinacea and muromonab-CD3 should be avoided.

**Reference:** Micromedex.

**Drug-Drug Interaction Monograph for PERJETA (Pertuzumab) #1**

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Pertuzumab/Perjeta |
| Class/Molecular weight: | Monoclonal Antibody/148 kDa |

**Victim drug:**
INN name/US brand name: Trastuzumab/Herceptin
Class/Molecular weight: Monoclonal Antibody/148 kDa

**Description of the effect of the DDI:**
No change in pharmacokinetic parameters or toxicity has been observed under co-administration of pertuzumab and trastuzumab.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
No clinical consequences have been observed.

**Clinical consequences:**
No dose adjustments have been recommended.

**Reference:** Perjeta prescribing information.

---

**Drug-Drug Interaction Monograph for PERJETA (Pertuzumab) #2**

---

**Perpetrator drug:**
INN name/US brand name: Pertuzumab/Perjeta
Class/Molecular weight: Monoclonal Antibody/148 kDa

**Victim drug:**
INN name/US brand name: Docetaxel/Taxotere
Class/Molecular weight: Chemotherapeutic/807.9 Da

**Description of the effect of the DDI:**
No change in pharmacokinetic parameters or toxicity has been observed under co-administration of pertuzumab and docetaxel.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
No clinical consequences have been observed.

**Clinical consequences:**
No dose adjustments have been recommended.

**Reference:** Perjeta prescribing information.

---

**Drug-Drug Interaction Monograph for PRIALT (Ziconotide Acetate)**

---

**Perpetrator drug:**
INN name/US brand name: Antidepressants, Anxiolytics, Antiepileptics,
Class/Molecular weight: Neuroleptics, Sedatives

**Victim drug:**
INN name/US brand name: Ziconotide Acetate/Prialt
Class/Molecular weight: Peptide/2.6 kD

**Description of the effect of the DDI:**
The use of drugs with CNS-depressant activities in conjunction with ziconotide acetate may be associated with an increased incidence of CNS-depressant effects.

*(Continued)*

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
The patient may experience cognitive impairment when ziconotide acetate is used in conjunction with CNS-depressant drugs due to the additive effects of the two therapies.

**Clinical consequences:**
It may be necessary to decrease the dose of the perpetrator medication.

**Reference:** Prialt prescribing information.

---

**Drug-Drug Interaction Monograph for PROLEUKIN (Aldesleukin) #1**

**Perpetrator drug:**
Class: Glucocorticoids

**Victim drug:**
INN name/US brand name: Aldesleukin/Proleukin
Class/Molecular weight: Cytokine/15.3 kDa

**Description of the effect of the DDI:**
Reduced antitumor effectiveness of aldesleukin with a concomitantly administered glucocorticoid.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
This is a class related pharmacodynamics interaction of unknown mechanism.

**Clinical consequences:**
NA

**Reference:** Proleukin prescribing information.

---

**Drug-Drug Interaction Monograph for PROLEUKIN (Aldesleukin) #2**

**Perpetrator drug:**
Class Antihypertensives

**Victim drug:**
INN name/US brand name: Aldesleukin/Proleukin
Class/Molecular weight: Cytokine/15.3 kDa

**Description of the effect of the DDI:**
Antihypertensives potentiate the hypotensive effects of aldesleukin.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
This is a class related pharmacodynamics interaction of unknown mechanism.

**Clinical consequences:**
Monitor patient's blood pressure.

**Reference:** Proleukin prescribing information.

---

**Drug-Drug Interaction Monograph for RAPTIVA (Efazulimab)**

**Perpetrator drug:**
INN name/US brand name: Efalizumab/Raptiva
Class/Molecular weight: Monoclonal Antibody/150 kDa

**Victim drug:**
Class/Molecular weight: Immunosuppressants

**Description of the effect of the DDI:**
Interactions have not been studied but an increased risk of infection or malignancy is expected.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Efalizumab and other immunosuppressants have concurrent mechanisms of action and increase the risk of toxicity.

**Clinical consequences:**
Do not coadminister efalizumab and immunosuppressants.

**Reference:** Raptiva prescribing information.

**Drug-Drug Interaction Monograph for REGRANEX (Becaplermin)**

**Perpetrator drug:**
INN name/US brand name: Becaplermin/Regranex
Class/Molecular weight: Peptide/25 kDa

**Victim drug:**
INN name/US brand name: NA
Class/Molecular weight:

**Description of the effect of the DDI:**
No drug-drug interaction studies have been performed.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
NA

**Clinical consequences:**
None

**Reference:** Regranex prescribing information.

**Drug-Drug Interaction Monograph for REMICADE (Infliximab) #1**

**Perpetrator drug:**
INN name/US brand name: Infliximab/Remicade
Class/Molecular weight: Chimeric Monoclonal Antibody/148 kDa

**Victim drug:**
INN name/US brand name: Abatacept/Orencia
Class/Molecular weight: Fusion Protein/92 kDa

*(Continued)*

**Description of the effect of the DDI:**
Concomitant administration of infliximab and abatacept appeared to increase the risk for severe infection.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
The increased risk of infection is hypothesized to be due to increased immunosuppression by TNF-alpha blockade if both drugs are given together.

**Clinical consequences:**
Infliximab should not be given concomitantly with abatacept.

**Reference:** Remicade prescribing information.

---

**Drug-Drug Interaction Monograph for REMICADE (Infliximab) #2**

---

**Perpetrator drug:**
INN name/US brand name: Infliximab/Remicade
Class/Molecular weight: Chimeric Monoclonal Antibody/148 kDa

**Victim drug:**
INN name/US brand name: Anakinra/Kineret
Class/Molecular weight: Recombinant Peptide/17 kDa

**Description of the effect of the DDI:**
Concomitant administration of infliximab and anakinra appeared to increase the risk for severe infection.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
The increased risk of infection is hypothesized to be due to increased immunosuppression by TNF-alpha blockade if both drugs are given together.

**Clinical consequences:**
Infliximab should not be given concomitantly with anakinra.

**Reference:** Remicade prescribing information.

---

**Drug-Drug Interaction Monograph for REOPRO (Abciximab)**

---

**Perpetrator drug:**
INN name/US brand name: Abciximab/Reopro
Class/Molecular weight: chimeric monoclonal antibody fragment/47.6 kDa

**Victim drug:**
INN name/US brand name: Heparin
Class/Molecular weight: Anticoagulant

**Description of the effect of the DDI:**
Increased risk of bleeding has been described.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
No change in pharmacokinetic parameters has been described. This appears to be a pharmacodynamic interaction.

**Clinical consequences:**
Use of heparin and abciximab during PTCA procedures should be monitored. Starting doses of heparin should not be higher than 70 IU/kg.

**Reference:** Reopro prescribing information.

The CAPTURE Investigators. Randomised placebo-controlled trial of abciximab before and during coronary intervention in refractory unstable angina: the CAPTURE Study. Lancet 1997, 349, 1429–35.

---

**Drug-Drug Interaction Monograph for SANDOSTATIN (Octreotide acetate)**

**Perpetrator drug:**
INN name/US brand name: Octreotide acetate/Sandostatin
Class/Molecular weight: Peptide/1.02 kDa

**Victim drugs:**
INN name/US brand name: Various small molecule drugs
Class/Molecular weight: Small molecules

**Description of the effect of the DDI:**
Increased risk of cardiotoxicity (QT prolongation, torsades de pointes, cardiac arrest)

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Additive effects on QT prolongation was the mechanism involved in drug interactions of Sandostatin with ziprasidone, bepridil, thioridazine, pimozide, terfenadine, mesoridazine, sparfloxacin, dronedarone, cisapride, levomethadyl, gemifloxacin, Phenothiazines, Erythromycin, Iloperidone, moxifloxacin, enflurane, apomorphine, perflutren lipid microsphere, pazopanib, ondansetron, trazodone, crizotinib, astemizole, spiramycin, solifenacin, fingolimod, mifepristone, vandetanib, sodium phosphate, clarithromycin, chloral hydrate, droperidol, telavancin, saquinavir, isoflurane, toremifene, pentamidine, foscarnet, salmeterol, domperidone, levofloxacin, class ia antiarrhythmics, antipsychotics, gatifloxacin, paliperidone, lidoflazine, dasatinib, telithromycin, chloroquine, artemether/lumefantrine, quinine, dolasetron, tricyclic antidepressants, voriconazole, arsenic trioxide, tetrabenazine,. methadone, clozapine, vardenafil, isradipine, norfloxacin, lopinavir/ritonavir, sorafenib, ofloxacin, cotrimoxazole, probucol, vasopressin, nilotinib, clomipramine, sunitinib, azithromycin, ciprofloxacin, class i antiarrhythmic agents, fluoxetine, lapatinib, asenapine, ranolazine, zolmitriptan, mefloquine, class iii antiarrhythmics, halofantrine, citalopram, fluconazole, posaconazole, halothane.

**Clinical consequences:**
Concomitant use of drugs with other drugs that prolong the QT interval, such as Sandostatin/octreotide is contraindicated due to the potential for additive effects on QT interval prolongation and an increased risk of serious ventricular arrhythmias, serious cardiac events including torsade de pointes.

**Reference:** Sandostatin prescribing information, Micromedex.

---

**Drug-Drug Interaction Monograph for SEROSTIM/SAIZEN (Somatropin)**

**See ACCRETROPIN (Somatropin) drug-drug interaction monographs #1– #4**

**Reference:** Serostim prescribing information
Saizen prescribing information

**Drug-Drug Interaction Monograph for SIMPONI (Golimumab) #1**

**Perpetrator drug:**
INN name/US brand name: Golimumab/Simponi
Class/Molecular weight: Human IgG1 monoclonal antibody/150 kDa

**Victim drugs:**
INN name/US brand name: Abatacept/Orencia
Class/Molecular weight: CTLA-4/human IgG1 Fc fusion protein/92 kDa

**Description of the effect of the DDI:**
Increased risk of serious infection.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Interference with the immune system at multiple levels.

**Clinical consequences:**
In controlled trials, the concurrent administration of another TNF-blocker and abatacept was associated with a greater proportion of serious infections than the use of a TNF-locker alone; and the combination therapy, compared to the use of a TNF-blocker alone, has not demonstrated improved clinical benefit in the treatment of psoriatic arthritis. Therefore, the combination of TNF-blockers including golimumab and abatacept is not recommended.

**Reference:** Simponi prescribing information, Micromedex.

**Drug-Drug Interaction Monograph for SIMPONI (Golimumab) #2**

**Perpetrator drug:**
INN name/US brand name: Golimumab/Simponi
Class/Molecular weight: Human IgG1 monoclonal antibody/150 kDa

**Victim drugs:**
INN name/US brand name: Anakinra/Kineret
Class/Molecular weight: recombinant, nonglycosylated form of the human interleukin-1 receptor antagonist/17.3 kDa
INN name/US brand name: Various
Class/Molecular weight: Live Vaccines

**Description of the effect of the DDI:**
Increased risk of serious infections and neutropenia.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Increased risk of serious infections has been seen in clinical rheumatoid arthritis studies of other TNF-blockers used in combination with anakinra, with no added benefit; therefore, use of golimumab with anakinra is not recommended. A higher rate of serious infections has also been observed in rheumatoid arthritis patients treated with rituximab who received subsequent treatment with a TNF-blocker. There is insufficient information to provide recommendations regarding the concomitant use of golimumab and other biologic products approved to treat rheumatoid arthritis or psoriatic arthritis.

**Clinical consequences:**
Concurrent administration of anakinra (an interleukin-1 antagonist) and another TNF-blocker was associated with a greater portion of serious infections and neutropenia and no additional benefits compared to TNF-blocker alone. Therefore, the combination of anakinra with TNF blockers, including golimumab, is not recommended.

**Reference:** Simponi prescribing information, Micromedex.

---

**Drug-Drug Interaction Monograph for SIMPONI (Golimumab) #3**

---

**Perpetrator drug:**
INN name/US brand name: Golimumab/Simponi
Class/Molecular weight: Human IgG1 monoclonal antibody/150 kDa

**Victim drugs:**
INN name/US brand name: Various
Class/Molecular weight: Live Vaccines

**Description of the effect of the DDI:**
Live vaccines: Increased risk of secondary transmission of infection by live vaccines.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
IgG antibodies are known to cross the placenta during pregnancy and have been detected in the serum of infants born to patients treated with these antibodies. Since golimumab is an IgG antibody, infants born to women treated with golimumab during their pregnancy may be at increased risk of infection for up to 6 months.

**Clinical consequences:**
Administration of live vaccines to infants exposed to golimumab *in utero* is not recommended for 6 months following the mother's last golimumab injection during pregnancy.

**Reference:** Simponi prescribing information, Micromedex

---

**Drug-Drug Interaction Monograph for SIMPONI (Golimumab) #4**

---

**Perpetrator drug:**
INN name/US brand name: Golimumab/Simponi
Class/Molecular weight: Human IgG1 monoclonal antibody/150 kDa

*(Continued)*

**Victim drugs:**

| | |
|---|---|
| INN name/US brand name: | Various |
| Class/Molecular weight: | CYP 450 substrates |

**Description of the effect of the DDI:**
Coadministration of Simponi may affect the clearance of concurrently administered CYP 450 substrates.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
The formation of CYP450 enzymes may be suppressed by increased levels of cytokines (e.g., TNF-$\alpha$) during chronic inflammation. Therefore, it is expected that for a molecule that antagonizes cytokine activity, such as golimumab, the formation of CYP450 enzymes could be normalized.

**Clinical consequences:**
Upon initiation or discontinuation of golimumab in patients being treated with CYP450 substrates with a narrow therapeutics index, monitoring of the effect (e.g., warfarin) or drug concentration, cyclosporine or theophylline) is recommended and the individual dose of drug product may be adjusted as needed.

**Reference:** Simponi prescribing information, Micromedex.

---

**Drug-Drug Interaction Monograph for SIMULECT (Basiliximab) #1**

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Basiliximab/Simulect |
| Class/Molecular weight: | Monoclonal antibody/143.8 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Tacrolimus/Prograf |
| Class/Molecular weight: | Immunosuppressant/804 Da |

**Description of the effect of the DDI:**
Concurrent use of basiliximab and tacrolimus may result in increased plasma tacrolimus trough concentrations and increased risk of tacrolimus toxicity.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Cytokine-induced alterations in CYP3A4-mediated metabolism of tacrolimus.

**Clinical consequences:**
Monitor tacrolimus plasma concentrations closely in patients receiving concomitant basiliximab treatment. Tacrolimus blood trough levels should be closely monitored 1 to 2 months post-transplant and dose-adjustments made as necessary.

**Reference:** Simulect labeling information.
Micromedex.

---

**Drug-Drug Interaction Monograph for SIMULECT (Basiliximab) #2**

**Perpetrator drug:**
INN name/US brand name: Echinacea
Class/Molecular weight: Herbal preparation

**Victim drug:**
INN name/US brand name: Basiliximab/Simulect
Class/Molecular weight: Monoclonal antibody/143.8 kDa

**Description of the effect of the DDI:**
Concurrent use of Echinacea and basiliximab may result in decreased effectiveness of basiliximab. Theoretically, Echinacea may antagonize the immunosuppressive effect of basiliximab. Human studies have shown an increase in granulocytes, monocytes, and lymphocytes in response to treatment with Echinacea, increased phagocytic activity, and increased natural killer cell function. Animals treated with Echinacea have shown increased immune response to antigens, and increased macrophage activation.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Immune system stimulation by Echinacea.

**Clinical consequences:**
Concomitant use of Echinacea and basiliximab should be avoided due to the antagonistic effect an immunostimulant such as echinacea may have on basiliximab, an immunosuppressant.

**Reference:** Simulect labeling information. Micromedex.

**Drug-Drug Interaction Monograph for SOLIRIS (Eculizumab)**

**Perpetrator drug:**
INN name/US brand name: Eculizumab/Soliris
Class/Molecular weight: Human monoclonal antibody/148 kDa

**Victim drugs:**
INN name/US brand name: Bioflavonoids; zinc glycinate; vitamin E; cholecalciferol, zinc sulfate
Class/Molecular weight: Vitamins and immunostimulants

**Description of the effect of the DDI:**
Drug interaction studies have not been performed with eculizumab.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Theoretically, agents that are thought to have immunostimulant properties such as echinacea, vitamin E and zinc may antagonize the pharmacologic effects of immunosuppressants.

**Clinical consequences:**
Clinical cases of drug interactions have not been reported.

**Reference:** Soliris prescribing information.

**Drug-Drug Interaction Monograph for SOMAVERT (Pegvisomat)**

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Pegvisomant/Somavert |
| Class/Molecular weight: | Recombinant protein/52 kDa |

**Victim drugs:**

| | |
|---|---|
| INN name/US brand name: | Octreotide/Sandostatin<br>Somatuline/Lanreotide |
| Class/Molecular weight: | Sandostatin: Cyclic octapeptide/1,02 kDa<br>Lanreotide: Cyclical octapeptide analog of the natural hormone, somatostatin/1,1 kDa |

**Description of the effect of the DDI:**
Concurrent use of octreotide or lanreotide and pegvisomant may result in elevated liver enzymes.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Concomitant use of somatostatin analogs, like octreotide and lanreotide, and pegvisomant may result in increased hepatic enzyme levels. Monitoring of liver function tests and appropriate dosage adjustment of pegvisomant is recommended during coadministration.

**Clinical consequences:**
Concomitant use of octreotide or lanreotide with pegvisomant may result in increased hepatic enzyme levels.

**Reference:** Somavert prescribing information, Micromedex.

**Drug-Drug Interaction Monograph for STELARA (Ustekinumab) #1**

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Ustekinumab/Stelara |
| Class/Molecular weight: | Human IgG1 monoclonal antibody/146 kDa |

**Victim drugs:**

| | |
|---|---|
| INN name/US brand name: | Various |
| Class/Molecular weight: | Live Vaccines |

**Description of the effect of the DDI:**
Concurrent use of ustekinumab and live vaccines may result in an increased risk of secondary transmission of infection by the live vaccine.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Altered cellular immune response.

**Clinical consequences:**
Although data are not available on the effects of concurrent vaccination, the manufacturer does not recommend the administration of live vaccines in patients receiving ustekinumab. Bacillus of Calmette and Guerin live vaccines should not be administered during treatment with ustekinumab or for 1 year prior to initiation or 1 year after discontinuation of ustekinumab.

**Reference:** Stelara prescribing information, Micromedex.

**Drug-Drug Interaction Monograph for STELARA (Ustekinumab) #2**

**Perpetrator drug:**
INN name/US brand name: Ustekinumab/Stelara
Class/Molecular weight: Human IgG1 monoclonal antibody/146 kDa

**Victim drugs:**
INN name/US brand name: Various
Class/Molecular weight: CYP 450 substrates

**Description of the effect of the DDI:**
Coadministration of Stelara may affect the clearance of concurrently administered CYP 450 substrates.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
The formation of CYP450 enzymes can be altered by increased levels of certain cytokines (e.g., IL-1, 289 IL-6, IL-10, TNFα, IFN) during chronic inflammation. Thus, ustekinumab, an antagonist of IL-12 and IL-23, could normalize the formation of CYP450 enzymes.

**Clinical consequences:**
Upon initiation of ustekinumab in patients who are receiving concomitant CYP450 substrates, particularly those with a narrow therapeutic index, monitoring for therapeutic effect (e.g., for warfarin) or drug concentration (e.g., for cyclosporine) should be considered and the individual dose of the drug adjusted as needed.

**Reference:** Stelara prescribing information, Micromedex.

**Drug-Drug Interaction Monograph for STIMATE (Desmopressin acetate)**

**See DDAVP (Desmopressin) drug-drug interaction monographs #1-#2**

**Reference:** Stimate prescribing information

**Drug-Drug Interaction Monograph for SYLATRON (Peginterferon)**

**Perpetrator drug:**
INN name/US brand name: Peginterferon alfa-2B/Sylatron
Class/Molecular weight: Recombinant interferon alfa-2b)/40 kDa

**Victim drug:**
Class: Drugs metabolized by CYP2C9 or CYP2D6

**Description of the effect of the DDI:**
When administering peginterferon alfa with medications metabolized by CYP2C9 or CYP2D6, the therapeutic effect of these drugs may be altered.

The coadministration of interferons and zidovudine may result in severe bone marrow toxicity, most often manifested as granulocytopenia and/or thrombocytopenia.

The risk of seizures may be increased during coadministration of tramadol or bupropion with any substance that can reduce the seizure threshold, including inferons. Interferons also exhibit CNS- and/or respiratory-depressant effects, which may be enhanced during their concomitant use with tramadol.

*(Continued)*

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
In a study in healthy subjects, a measure of CYP2C9 activity increased to 125% (90% CI: 116% to 135%) of baseline, whereas a measure of CYP2D6 activity decreased to 51% (90% CI: 38% to 67%) of baseline when coadministered with peginterferon alfa-2b at 1 mcg/kg/week. A measure of CYP1A2 and CYP3A4 activity did not show clinically meaningful changes.

Interferons and zidovudine agents are individually myelotoxic, with potentially additive or synergistic effects.

**Clinical consequences:**
Close monitoring for drugs metabolized by CYP2C9 or CYP2D6.

Caution is advised if concomitant therapy is necessary, particularly with the alfa interferons. Complete blood counts, differential and platelet counts should be performed regularly and drug dosages adjusted accordingly. Patients should be advised to promptly report symptoms such as chills, fever, sore throat, pale skin, or unusual fatigue to their physician. Cessation of one or all drugs may be necessary if toxicity develops

Caution is advised if tramadol or bupropion is administered with any substance that can reduce the seizure threshold such as interferons, particularly in the elderly and in patients with epilepsy, a history of seizures, or other risk factors for seizures (e.g., head trauma, brain tumor, metabolic disorders, alcohol and drug withdrawal, CNS infections).

**Reference:** Sylatron prescribing information.

---

**Drug-Drug Interaction Monograph for SYNAGIS (Palivizumab)**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Palivizumab/Synagis |
| Class/Molecular weight: | Humanized IgG1 monoclonal antibody/148 kDa |

**Victim drug:**

| | |
|---|---|
| Class: | Abciximab/Reopro; Belimumab/Benlysta |
| Class/Molecular weight: | Monoclonal antibodies |

**Description of the effect of the DDI:**
When abciximab or belimumab is used in combination with palivizumab, drug interactions could occur. As a result, the risk for allergic reactions, infections, or low blood cell counts can increase.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
If patients received abciximab in the past, they may have developed antibodies to the medication. These antibodies can increase the chance of having an allergic reaction to Synagis or other monoclonal antibody medications.

Using palivizumab with belimumab may increase the risk for side effects, such as infection or low blood cell counts.

**Clinical consequences:**
No specific recommendations.

**Reference:** Synagis prescribing information.

---

**Drug-Drug Interaction Monograph for TEV-TROPIN (Somatropin)**

**See ACCRETROPIN (Somatropin) drug-drug interaction monographs #1– #4**

**Reference:** Tev-Tropin prescribing information

**Drug-Drug Interaction Monograph for TNKASE (Tenecteplase)**

**Perpetrator drug:**

INN name/US brand name: Tenecteplase/TNKase
Class/Molecular weight: Enzyme/58.9 kDa

**Victim drug:**

Class: Low molecular-weight heparins (enoxaparin, dalteparin, parnaparin, nadroparin, reviparin, tinzaparin, ardeparin, and certoparin)

Class: Anticoagulants (heparin, drotrecogin alfa, dabigatran, warfarin, phenprocoumon, phenindione, acenocoumarol, danaparoid, bivalirudin, argatroban, lepirudin, desirudin, fondaparinux, rivaroxaban, protein C (Human)).

Class: Platelet aggregation inhibitors (acetylsalicylic acid, dipyridamole, GP IIb/IIIa inhibitors, ticlopidine)

Class: Thrombolytic agents (streptokinase, urokinase, alteplase, anistreplase, reteplase, lepirudin)

**Description of the effect of the DDI:**
Increasing risk of bleeding might be observed if anticoagulants and drugs that alter platelet function are administered prior to, during, or after TNKase therapy.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
NA

**Clinical consequences:**
Monitor for signs of bleeding.

**Reference:** Tnkase prescribing information, Micromedex.

**Drug-Drug Interaction Monograph for TRASYLOL (Aprotinin) #1**

**Perpetrator drug:**

INN name/US brand name: Aprotinin/Trasylol
Class/Molecular weight: Bovine proteinase inhibitor/6.5 kDa

**Victim drug:**

Class: Fibrinolytic agents

*(Continued)*

**Description of the effect of the DDI:**
Aprotinin is known to have antifibrinolytic activity and, therefore, may inhibit the effects of fibrinolytic agents.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
NA

**Clinical consequences:**
No specific recommendations are available.

**Reference:** Trasylol prescribing information.

---

**Drug-Drug Interaction Monograph for TRASYLOL (Aprotinin) #2**

---

**Perpetrator drug:**
INN name/US brand name: Aprotinin/Trasylol
Class/Molecular weight: Bovine proteinase inhibitor/6.5 kDa

**Victim drug:**
INN name/US brand name: Captopril/Capoten
Class/Molecular weight: Small molecule

**Description of the effect of the DDI:**
In study of nine patients with untreated hypertension, aprotinin infused intravenously in a dose of 2 million KIU over two hours blocked the acute hypotensive effect of 100 mg of captopril.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
NA

**Clinical consequences:**
No specific recommendations are available.

**Reference:** Trasylol prescribing information.

---

**Drug-Drug Interaction Monograph for TRASYLOL (Aprotinin) #3**

---

**Perpetrator drug:**
INN name/US brand name: Aprotinin/Trasylol
Class/Molecular weight: Bovine proteinase inhibitor/6.5 kDa

**Victim drug:**
INN name/US brand name: Heparin
Class/Molecular weight: Carbohydrate/12–15 kDa

**Description of the effect of the DDI:**
Aprotinin, in the presence of heparin, has been found to prolong the activated clotting time

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Aprotinin prolongs whole blood clotting times by a different mechanism than heparin. In the presence of aprotinin, prolongation is dependent on the type of whole blood clotting test employed. If an activated clotting time (ACT) is used to determine the effectiveness of heparin anticoagulation, the prolongation of the ACT by aprotinin may lead to an overestimation of the degree of anticoagulation, thereby leading to inadequate anticoagulation.

**Clinical consequences:**
No specific recommendations are available.

**Reference:** Trasylol prescribing information.

---

**Drug-Drug Interaction Monograph for TYSABRI (Natalizumab) #1**

---

**Perpetrator drug:**
INN name/US brand name: Interferon beta-1a/Avonex
Class:/Molecular weight: Protein/20.0 kDa

**Victim drug:**
INN name/US brand name: Natalizumab/Tysabri
Class/Molecular weight: Monoclonal Antibody/149 kDa

**Description of the effect of the DDI:**
Natalizumab exposure parameters (i.e., $C_{max}$, AUC) and terminal elimination half-life appeared to be somewhat higher when administered in combination with interferon beta 1a. $C_{max}$ increased from 151.9 to 174.2 μg/L while the half-life increased from 142.6 to 175.3 h.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
No dose adjustments have been recommended.

**Clinical consequences:**
No clinical consequences have been observed

**Reference:** Tysabri prescribing information.

Vollmer et al. An open-label safety and drug interaction study of natalizumab (Antegren™) in combination with interferon-beta (Avonex®) in patients with multiple sclerosis. Mult Scler. 2004;10(5):511–20.

---

**Drug-Drug Interaction Monograph for TYSABRI (Natalizumab) #2**

---

**Perpetrator drug:**
INN name/US brand name: Immunosuppressants

**Victim drug:**
INN name/US brand name: Natalizumab/Tysabri Change formatting
Class/Molecular weight: Monoclonal Antibody/149 kDa

**Description of the effect of the DDI:**
Because of the potential for increased risk of PML(Progressive multifocal leukoencephalopathy) and other infections, Crohn's disease patients receiving natalizumab should not be treated with concomitant immunosuppressants (e.g., 6- mercaptopurine, azathioprine, cyclosporine, or methotrexate) or inhibitors of TNF-α. Corticosteroids should be reduced in patients with Crohn's disease who will begin with natalizumab therapy.

**Description of the mechanism of the DDI:**
NA

*(Continued)*

**Clinical consequences:**
In Crohn's disease clinical studies, opportunistic infections (*Pneumocystis carinii* pneumonia, pulmonary *Mycobacterium avium intracellulare*, bronchopulmonary aspergillosis, and *Burkholderia cepacia*) have been observed in <1% of TYSABRI-treated patients; some of these patients were receiving concurrent immunosuppressants.

Multiple Sclerosis patients receiving chronic immunosuppressant or immunomodulatory therapy should not be treated with natalizumab.

**Reference:** Tysabri prescribing information.

**Drug-Drug Interaction Monograph for ULTRESA/[Pancrelipase(Amylase, lipase, protease)]**

---

**Perpetrator drug:**
INN name/US brand name: Pancrelipase/Ultresa
Class/Molecular weight: Enzyme mixture/~131 kDa

**Victim drug:**
INN name/US brand name: L-Methylfolate
Class/Molecular weight: Small Molecule/459 Da

**Description of the effect of the DDI:**
Concurrent use of L-methylfolate and pancrelipase may result in decreased L-methylfolate serum concentrations.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Decreased folate absorption.

**Clinical consequences:**
No clinical consequences have been observed.

**Reference:** Micromedex.

---

**Drug-Drug Interaction Monograph for VORAXAZE (Glucarpidase)**

---

**Perpetrator drug:**
INN name/US brand name: Leucovorin/Wellcovorin
Class/Molecular weight: Folate Analog

**Victim drug:**
INN name/US brand name: Glucarpidase/Voraxaze
Class/Molecular weight: Homodimer Protein/83 kDa

**Description of the effect of the DDI:**
Coadministration of leucovorin and glucarpidase results in increased plasma concentrations of methotrexate.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Leucovorin competes with methotrexate for the same binding sites on glucarpidase. This action diminishes the efficacy of glucarpidase in decreasing elevated methotrexate concentrations.

**Clinical consequences:**
Do not give leucovorin within 2 hours of glucarpidase administration.

**Reference:** Voraxaze prescribing information.

---

**Drug-Drug Interaction Monograph for WYDASE (Hyaluronidase)**

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Hyaluronidase/Wydase |
| Class/Molecular weight: | Enzyme/53.9 kDa |

**Victim drug:**

| | |
|---|---|
| Class: | Anesthetics (Mepivacaine, bupivacaine, benzocaine, etidocaine, cocaine, lidocaine, propxycaine, tetracaine, ropivacaine, bucaine, proparacaine, dibucaine, procaine, chloroprocaine, prilocaine) |

**Description of the effect of the DDI:**
Concurrent use of anesthetics and hyaluronidase may result in an increased incidence of a systemic reaction to the anesthetic.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Hyaluronidase increases the duration of anesthetics in inferior alveolar nerve blocks.

**Clinical consequences:**
Monitor patients for local anesthetic toxicity. Hyaluronidase effectively increases topical diffusion of local anesthetics. However, due to its propensity to increase the incidence of systemic reactions to local anesthetics and because there are newer anesthetic agents which penetrate very effectively, its use can no longer be justified.

**Reference:** Horliana TAC, et al. Hyaluronidase increases the duration of mepivacaine in inferior alveolar nerve blocks. J Oral Maxillofac Surg. 2008;66(2):286–90.
Micromedex.

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Denosumab/Xgeva |
| Class/Molecular weight: | Human IgG2 Monoclonal Antibody/147 kDa |

**Victim drug:**

| | |
|---|---|
| Class: | Anticancer chemotherapeutics |

**Description of the effect of the DDI:**
No change in pharmacokinetic parameters or toxicity has been observed under co-administration of denosumab and anticancer agents.

Serum denosumab concentrations at 1 and 3 months were not altered by concomitant chemotherapy.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
No dose adjustments have been recommended.

**Clinical consequences:**
No clinical consequences have been observed

**Reference:** Xgeva prescribing information.

**Drug-Drug Interaction Monograph for XIAFLEX (Collagenase *Clostridium histolyticum)***

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Collagenase *Clostridium histolyticum*/Xiaflex |
| Class/Molecular weight: | Two polypeptides/114 kDa and 113 kDa |

**Victim drug:**

| | |
|---|---|
| Class: | Anticoagulants |

**Description of the effect of the DDI:**
Possibility of developing an ecchymosis/contusion or an injection site hemorrhage.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Additive anticoagulation.

**Clinical consequences:**
Collagenase should be used with caution in patients receiving concomitant anticoagulants (except for low-dose aspirin).

**Reference:** Xiaflex prescribing information.

**Drug-Drug Interaction Monograph for XIGRIS (Drotrecogin alfa)**

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Drotrecogin alfa/Xigris |
| Class/Molecular weight: | Glycoprotein/55 kDa |

**Victim drug:**

| | |
|---|---|
| Class: | Anticoagulants |

**Description of the effect of the DDI**
Concurrent use of drotrecogin alfa and anticoagulants may result in increased risk of bleeding.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Additive anticoagulation.

**Clinical consequences:**
Use caution with coadministration of drotrecogin alfa and anticoagulants in therapeutic dosages for thromboembolism. No drotrecogin alfa dosage adjustment is necessary when coadministered with heparin using the prophylactic doses for venous thromboembolism.

**Reference:** Xigris prescribing information.

**Drug-Drug Interaction Monograph for ZALTRAP (Ziv-Aflibercept) #1**

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Ziv-Aflibercept/Zaltrap |
| Class/Molecular weight: | Recombinant fusion protein/155 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Irinotecan/Camptosar |
| Class/Molecular weight: | Antineoplastic agent/677.2 Da |

**Description of the effect of the DDI:**
No change in pharmacokinetic parameters or toxicity has been observed under co-administration of ziv-aflibercept and irinotecan.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
No dose adjustments have been recommended.

**Clinical consequences:**
No clinical consequences have been observed.

---

**Drug-Drug Interaction Monograph for ZENAPAX (Daclizumab) #1**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Daclizumab/Zenapax |
| Class/Molecular weight: | Humanized IgG1 Monoclonal Antibody/144 kDa |

**Victim drug:**

| | |
|---|---|
| Class: | Immunosuppressive agents (cyclosporine, mycophenolate mofetil, ganciclovir, acyclovir, azathioprine, corticosteroids) |

*(Continued)*

**Description of the effect of the DDI:**
In cardiac transplant recipients (n = 434) receiving concomitant cyclosporine, mycophenolate mofetil, and corticosteroids, mortality was increased in patients randomized to receive daclizumab compared with those randomized to receive placebo.

The concomitant administration of daclizumab and mycophenolate mofetil had no effect on the pharmacokinetics of mycophenolic acid.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
No dose adjustments have been recommended.

**Clinical consequences:**
No clinical interventions have been recommended.

**Reference:** Zenapax prescribing information.

---

**Drug-Drug Interaction Monograph for ZENAPAX (Daclizumab) #2**

---

**Perpetrator drug:**

| | |
|---|---|
| Class: | Anti-Lymphocyte Antibody<br>Antibody/144 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Daclizumab/Zenapax |
| Class/Molecular weight: | Immunosuppressive, Humanized IgG1 Monoclonal |

**Description of the effect of the DDI:**
The use of daclizumab was associated with a higher incidence of mortality in patients receiving concomitant anti-lymphocyte antibody therapy, compared to placebo, in a large (n = 434) randomized controlled study of patients receiving cardiac transplants.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
No dose adjustments have been recommended.

**Clinical consequences:**
No clinical interventions have been recommended.

**Reference:** Zenapax prescribing information.

---

**Drug-Drug Interaction Monograph for ZEVALIN (Ibritumomab tiuxetan)**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Ibritumomab tiuxetan/Zevalin |
| Class/Molecular weight: | Immunoconjugate between monoclonal antibody and linker-chelator/148 kDa |

**Victim drug:**

| | |
|---|---|
| Class: | Anticoagulants/Antiplatelet agents |

**Description of the effect of the DDI:**
Concurrent use of ibritumomab tiuxetan and anticoagulants/antiplatelet agents may result in an increased risk of bleeding and hemorrhage.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
NA

**Clinical consequences:**
Monitor for thrombocytopenia more frequently when using ibritumomab and anticoagulants/antiplatelet agents concomitantly. The transfusion practices may need to be modified.

**Reference:** Zevalin prescribing information.

---

**Drug-Drug Interaction Monograph for ZOLADEX (Goserelin Acetate)**

**Perpetrator drug:**
INN name/US brand name: Goserelin Acetate/Zoladex
Class/Molecular weight: Decapeptide/1,269 Da

**Victim drug:**
INN name/US brand name: Tamoxifen Citrate/Nolvadex
Class/Molecular weight: Nonsteroidal Antiestrogen/563.6 Da

**Description of the effect of the DDI:**
The effect of concurrent goserelin and tamoxifen in treating premenopausal women with early breast cancer is not clear, but may have less benefit than a mono therapy.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
No change in pharmacokinetic parameters or toxicity has been observed under co-administration of goserelin and tamoxifen.

**Clinical consequences:**
The combination of goserelin and tamoxifen reduces the risk of first event by 24%, compared to 32% with goserelin and 27% with tamoxifen alone.

**Reference:** Zoladex prescribing information.

## 1.1 INTRODUCTION

Bringing a drug only to target tissues without spilling any molecule in unwanted places would be an ideal goal for any pharmacological therapies [1]. Owing to the dose-limiting side effects of chemotherapy, a number of drug delivery strategies have been developed in the context of cancer, where "targeted" therapy is most anticipated. Most tumor-targeted drug delivery systems are based on the fact that cancer cells express various molecular markers that are distinguished from those of normal cells. In particular, nanomedicines have received enormous attention in the past decades as a potential tool to increase the selectivity of chemotherapy and diagnosis, due to the small size conducive to circulation and the large surface area to volume ratio that facilitates surface functionalization. Several nanomedicine products have been launched in the market or in the clinical development stage as summarized in Table 1.1. Newer approaches are actively developed to increase target selectivity, although the number of targeted nanomedicines that reached the later phase of

**TABLE 1.1 Nanomedicines on the Market or in Phase II/III Clinical Development**

| Type of Nanoparticles | Formulation | Drug | Brand Name (Company) | Indication(s) | Current Status and Reference |
|---|---|---|---|---|---|
| Lipid-based or liposomes | Lipid–drug complex | Amphotericin B | Abelcet (Sigma-Tau) | Antimicrobial | Market [3] |
| | PEGylated liposome | Doxorubicin | Doxil and Caelyx (Janssen) | Breast cancer, ovarian cancer, multiple myeloma, Kaposi's sarcoma | Market [4] |
| | Non-PEGylated liposome | Doxorubicin | Myocet (Enzon) | Breast cancer | Market [5] |
| | Non-PEGylated liposome | Daunorubicin | DaunoXome (Galen) | Kaposi's sarcoma | Market [6] |
| | Non-PEGylated liposome | Cytarabine | DepoCyt (Sigma-Tau) | Lymphomatus meningitis, leukemia, glioblastoma | Market [7] |
| | Non-PEGylated liposome | Amphotericin B | Ambisome (Gilead) | Fungal infection, cryptococcal meningitis | Market [8] |
| | PEGylated liposome | Cisplatin | Lipoplatin (Regulon) | Various malignancies | Phase III, investigational drug [9–13] |
| | Heat-activated PEGylated liposome | Doxorubucin | Thermodox (Celsion Corporation) | Hepatocellular carcinoma, recurrent chest wall breast cancer | Phase III [14] |
| | Sphingomyelin-based liposomes | Vincristine sulfate (targeted, Optisome™, details not provided) | Marqibo® (Talon Therapeutics) | Non-Hodgkin's lymphoma | NDA submitted [15,16] |
| Albumin-bound particles | Albumin bound nanoparticle | Paclitaxel (Albumin) | Abraxane® (Astellas) | Breast cancer | Market [17,18] |
| Polymer-drug/protein/nucleic acid conjugates | PEG conjugated | L-Asparaginase | Oncaspar® (Sigma-Tau) | Acute lymphoblastic leukemia | Market [19] |
| | Poliglumex (poly-L-glutamic acid) conjugated | Paclitaxel | Opaxio™ or previously Xyotax (Cell Therapeutics Inc.) | Nonsmall cell lung cancer, ovarian cancer | Phase III [20–23] |

| | | | | | |
|---|---|---|---|---|---|
| | Conjugated with uniquely engineered macromolecular polymer core using specialized linkers | Irinotecan | Etirinotecan Pegol (Nektar Therapeutics) | Breast cancer, ovarian cancer, colorectal cancer | Phase III [24] |
| | PEGylated anti-VEGF aptamer | Pegaptanib sodium (VEGF) | Macugen (Eyetech, Inc.) | Age-related macular degeneration | Market [25] |
| | PEG conjugated | Recombinant human granulocyte colony-stimulating factor | Neulasta (Amgen) | Prevention of chemotherapy-associated neutropenia | Market [26] |
| Polymeric micelles | Methoxy PEG-PLA copolymer micelle | Paclitaxel | Genexol-PM® (Samyang Co.) | Breast cancer, lung cancer, ovarian cancer | Phase II [27,28] |
| Nanocrystals | Nanocrystal drug particles | Aprepitant | Emend (Merck) | Antiemetic | Market [29] |
| | Nanocrystal drug particles | Sirolimus | Rapamune (Pfizer) | Immunosuppressive | Market [29] |
| | Nanocrystal drug particles | Fenofibrate | Tricor (Abbott) | Hypercholesterolemia or mixed dyslipidemia | Market [29] |
| | Nanocrystal drug particles | Megestrol acetate | Megace ES (BMS) | Synthetic progestin | Market [29] |
| Dendrimers | Carbopol® gel (cross-linked acrylic acid) | SPL7013 (antimicrobial agent) | VivaGel (Starpharma, Dendritic Nanotechnologies Inc., United States) | Bacterial vaginosis | Market, Phase III [3,30] |
| Cyclodextrin-based nanoparticles | Transferrin receptor-targeted cyclodextrin NPs, RONDEL™ | siRNA targeting the M2 subunit of ribonucleotide reductase | CALAA-01 (Calando Pharmaceuticals) | Inhibition of tumor growth | Phase I trial, [31,32] |
| Inorganic nanoparticles | Streptavidin covalently attached to quantum nanocrystals (QDot) | — | Qdot® 800 Streptavidin Conjugate (Invitrogen) | Imaging, diagnostics, detection of proteins, nucleic acids | Market [33,34] |
| | Superparamagnetic iron oxide nanoparticles coated with carboxydextran | — | Resovist (Schering) | Hepatocellular carcinoma | Market [35] |
| | Iron nanoparticles | — | Feridex (AMAG Pharmaceuticals) | Detection of liver lesions | Market [36] |

*Notes:* The table was created through internet search, product websites, and previously published articles [37,38]. Antibody–drug conjugates are omitted, but some publications list them under nanomedicine [38].

clinical trials is relatively low considering the prevalent excitement and the investment made till date [2].

This chapter discusses the rationale of targeted nanomedicines, different approaches to achieve this goal, current challenges, and considerations for their future development. Here, nanomedicines refer to particulate materials with a diameter in nanometer scale, prepared with natural or synthetic polymers, lipids, or inorganic solids, in the form of polymer–drug conjugates, liposomes, polymeric nanoparticles (NPs) or micelles, dendrimers, nanotubes, nanocrystals, nanorods, nanoshells, or nanocages [2]. Nanomedicines used as a carrier of a drug are often called nanocarriers. Nanoparticles and nanocarriers are also interchangeably used. We will use the term "nanoparticles" to represent various types of nanocarriers in this chapter.

## 1.2 FUNCTIONS OF NANOPARTICLES

Fates of a drug entering circulation largely depend on the properties of the drug. Small hydrophilic drug molecules do not bind to proteins in the blood and are quickly eliminated from the body. Hydrophobic drugs are eliminated relatively slowly through kidneys due to plasma protein binding, metabolized in the liver to a hydrophilic metabolite, and then eliminated from the body. On the other hand, the disposition and clearance of drugs encapsulated in NPs depend relatively less on the drug itself than on the properties of NPs during circulation [39].

Systemically administered NPs should be stable enough to retain a drug during circulation and able to extravasate at the target tissues and release the drug in the target tissues and/or inside the target cells to exert an action. Advancement in the nanotechnology has made it possible to incorporate therapeutic drugs in various types of NPs. NPs have contributed to the delivery of poorly water-soluble drugs and improving the bioavailability of drugs with poor stability [2,40,41]. One of the major concerns in cancer chemotherapy is multidrug resistance as most anticancer drugs are substrates of drug efflux transporters such as P-glycoprotein. NPs can be designed to overcome the resistance by bypassing efflux transporters [2,42]. Most significantly, NPs have gained enormous interest as a way of increasing drug delivery to target tissues, in particular, tumors. A detailed discussion of the use of NPs in drug delivery is available in other review articles [2,43].

NPs can be combined with contrast or imaging agents to visualize pathological tissues and monitor the progression of diseases [44]. Liposomes, micelles, and dendrimers are used to carry paramagnetic ions of indium-111 ($^{111}$In), technetium ($^{99m}$Tc), manganese (Mn), and gadolinium (Gd). Semiconductor quantum dots or gold NPs have been widely explored for target-specific imaging as combined with various functionalization strategies [45–47].

## 1.3 TUMOR-TARGETED NANOPARTICLES

Several strategies have been employed to achieve tumor-targeted drug delivery based on NPs. We briefly introduce these targeting strategies before we discuss challenges in translating NPs to commercial products.

### 1.3.1 Passive Targeting

Delivering anticancer agents to the tumors is a multistep process. Drugs delivered into the bloodstream should reach intratumoral region from systemic circulation by crossing tumor vasculature so that drug molecules have access to the tumor cells and stroma. Many solid tumors are characterized by leaky vasculature and poor lymphatic drainage [43]. New vasculature in the tumor is formed to sustain the tumor growth and provide nutrients; however, the structure is usually abnormal and defective with holes ranging from 400 to 600 nm in diameter [48–50]. The defective structure of blood vessels surrounding tumors allows NPs to extravasate and accumulate in the tumor tissues. The impaired lymphatic drainage further helps retain NPs in the tumors. Therefore, NPs with a size less than the cutoff of holes in the vasculature have a selective advantage in reaching tumors. This phenomenon is referred to as the enhanced permeability and retention (EPR) effect [51–53].

For NPs to take advantage of the EPR effect, it is important that the NPs circulate for a long period of time. It is widely known that NPs with hydrophobic or charged surfaces are readily opsonized and taken up by the reticuloendothelial system (RES), which is responsible for clearing macromolecules or particles present in the blood before they reach the target tissues [54,55]. Therefore, most NPs are surface-modified with a hydrophilic and electrically neutral polymer such as polyethylene glycol (PEG) (PEGylated) [54,56,57]. The PEGylated surface is resistant to protein binding and thus avoids the recognition by the RES [55,58,59]. For long-term circulation and effective extravasation via leaky vasculature of tumors, ~50–300 nm is considered an optimal size [60,61].

### 1.3.2 Active Targeting

Active targeting strategy was developed to further enhance tumor accumulation of NPs beyond the level possible with long-circulating NPs. Here, NP surface is decorated with targeting ligands that can actively bind to cell receptors overexpressed on the tumor cells [2,49,62–65]. Frequently used targeting ligands include antibodies, peptides, nucleic acids, and small molecular weight ligands binding to specific receptors [2,65,66]. For example, NPs are conjugated with the monoclonal antibody teratuzumab or herceptin to target HER2 receptor on breast cancer cells [59,67]. A docetaxel-NP formulation containing a small molecule ligand which targets prostate-specific membrane antigen has recently entered a Phase I clinical trial [68].

The rationale of active targeting is that a specific interaction between targeting molecules and cell receptors will increase the amount of NPs retained in tumors. An example is shown in a biodistribution study of $^{111}$In-labeled polymeric micelle NPs [69]. Nontargeted NPs (25 nm) were rapidly cleared from plasma as compared to nontargeted NPs with a size of 60 nm, resulting in twofold less total tumor accumulation. On the other hand, another 25 nm NPs functionalized with epidermal growth factor achieved a greater tumor accumulation than nontargeted ones in mice with tumors overexpressing EGF-receptors, reaching the same level as that of 60 nm nontargeted NPs [69]. However, it should be borne in mind that the

contribution of a targeting ligand is predicated on the extravasation of NPs to the tumors; thus, the ability to survive circulation for a long period of time still remains one of the most important requirements in the active targeting strategy. For effective active targeting, the density of target receptors should be in range of $10^4$ or $10^5$ copies per cell [2,70]. In addition to the number of binding sites, binding affinity also plays an important role. Multivalency of ligands can further enhance the affinity for target cells [71]. Receptors in a cell are internalized via different pathways and go through a continuous process of recycling [72]. NPs with targeting ligands can be internalized via the receptor-mediated endocytosis pathways and release drugs inside the cells.

### 1.3.3 Target-Activated Systems

Target-activated systems refer to NPs that remain stable until they reach target tissues and are activated by the extracellular or intracellular cues [64,73]. The NPs are designed to circulate similar to passively targeted NPs and transform to a more cell-interactive form in response to conditions unique to tumor tissues or intracellular environments. These conditions include acidic pH or enzymes abundant in the tumor extracellular matrix (ECM).

***1.3.3.1 pH-Activated Systems.*** NPs responsive to acidic pH can be classified into two categories: one activated in the tumor ECM, which may have a pH as low as ~6, and the other activated in the intracellular lysosomes, which acidifies to pH 4–5. Tumors exhibit a slightly acidic pH in the range 6.8–7.2 compared to the physiological pH of 7.4 [74]. This acidity is due to the accumulation of lactic acid, induced by the increased glycolysis of tumor cells [75]. The acidosis of tumor is further enhanced as tumors develop hypoxia, which induces or selects for hyperglycolic cells [76]. The pH-sensitive NPs are composed of polymers, which are protonated at acidic pHs. Upon protonation of the polymer, the NPs are disintegrated to release drugs or change the surface properties to enter cells [64,77].

Most NPs entering cells via receptor-mediated endocytosis pathways end up in endosomes, which undergo a maturation process into late endosomes and lysosomes [72]. The luminal pH in these vesicles is acidic, varying from pH 6 (endosomes), pH 5–6 (late endosomes), to pH 4.5 (lysosomes) [72]. NPs are designed to escape the vesicles and/or release the payload in response to the low pH. Polycationic polymers such as polyethyleneimine or fusogenic peptides can be used in the formulations [78]. On entering the cell, a drug should reach its final destination to produce an action, which can be a nucleus or other organelles such as mitochondria, lysosome, and endoplasmic reticulum. NP trafficking to the specific organelles may be achieved by the use of specific peptide sequences [47,79].

***1.3.3.2 Enzymatically Activated Systems.*** Enzymes overexpressed in the tumor microenvironment are used for activating the NPs at tumor sites. An example of such enzymes is matrix metalloproteinases (MMPs) [80,81], which play a critical role in the invasion of tumor cells and angiogenesis [82]. Several studies have employed

MMPs for removing the PEG protection of NP surface at the tumor sites [83–85]. In these approaches, PEG is linked to the NP surface via a peptide linker sensitive to MMPs. Recently, cathepsin B has been utilized to activate a nanoprobe in a tumor-specific manner [86]. Cathepsin B is a lysosomal cysteine protease that plays a role in tumor progression [87]. The nanoprobe consists of glycol chitosan conjugated with a cathepsin B substrate peptide, a near infrared fluorescent dye, and a dark quencher, which self-assemble into 280 nm NPs. Upon the entrance into tumor cells, the cathepsin B substrate peptide is cleaved by intracellular cathepsin B, allowing for dequenching of the dye and emission of the fluorescence signals [86].

## 1.4 REMAINING CHALLENGES IN THE DEVELOPMENT OF TUMOR-TARGETED NANOPARTICLES

Several NP products, such as liposomes and polymer–drug conjugates, are currently in the market or in the late stage of development process, improving therapeutic efficacy and safety profiles of chemotherapeutics [36,40]. A large number of targeted NPs have been developed in the last three decades in an attempt to further improve the efficacy of NP-based therapy. However, several challenges remain to be overcome for developing NPs that can attract commercial interest and achieve significant clinical outcomes. Current limitations and challenges in the advancement of nanomedicine have been thoroughly discussed in recent review articles [36,60,88–92].

### 1.4.1 NP Stability

Stability of circulating NPs matters in at least two contexts. NPs carrying a drug must survive the body's natural ability to clear the NPs and should be able to retain a drug during circulation. The former requirement is largely addressed by surface modification with a "stealth" coating with polymers such as PEG. However, recent studies have identified potential disadvantages of PEG [73]. For example, PEG can interfere with NP–cell interactions [93] and endosomal escape of NPs [93] after the disposition of NPs. It is also suggested that PEGylated liposomes are implicated with immune responses, which lead to an accelerated blood clearance of the second dose liposomes [94,95]. Alternative polymers or surface protection strategies are actively explored [73].

Stable retention of a drug during circulation is another important challenge. Despite the thermodynamic stability in buffers, some polymeric micelles or matrix-type NPs have been shown to quickly disintegrate and/or leak the payload upon contact with various blood components [64,96–98]. Chen et al. demonstrated that polymeric micelles composed of PEG-poly(D,L-lactic acid) block-copolymer dissociated and released the encapsulated fluorescent dyes within 15 min after intravenous injection [96]. Another study showed that a drug and the carrier (liposomes) exhibited different pharmacokinetics in blood, indicating that the drug was escaping the carrier prematurely [99]. The instability of NPs in circulation is a significant (yet often neglected) problem in the development stage. Success of a new NP system

depends on the availability of a method that can reliably predict the stability of NPs in a biological environment.

### 1.4.2 Heterogeneous Tumor Vasculature

Tumor accumulation of NPs mainly depends on their passive extravasation via the leaky vasculature feeding the tumors. While the defective architecture of tumor vasculature is widely exploited by the NP-based drug delivery, it is often ignored that the tumor blood vessels are heterogeneous [100,101] and do not exhibit the same degree of leakiness [102]. The heterogeneity of the EPR effect is even greater when different tumor models are compared. A biodistribution study of $^{111}$In-labeled PEGylated liposomes in 17 patients with locally advanced cancers showed that the levels of tumor liposome uptake varied from 0.5% to 3.6% of injected dose (ID) at 72 h, which translated into 2.7–53% of ID/kg of tumor (ID/kg) [103]. This study also showed that the tumor uptake of liposomes varied significantly with the site of the primary tumors, from $5.3 \pm 2.6\%$ ID/kg in breast cancers, $18.3 \pm 5.7\%$ ID/kg in lung tumors, to $33.0 \pm 15.8\%$ ID/kg in head and neck cancers [103]. Therefore, NPs relying on the EPR effect alone are unlikely to achieve reliable and predictable clinical outcomes.

### 1.4.3 NP Distribution in Tumors

The lack of functional lymphatics and the high vascular permeability result in elevation of the pressure in the interstitial tissue of solid tumors [104]. Furthermore, tumors develop various conditions to increase the stiffness of tissue [105]. The high interstitial fluid pressure and the stiffness of the tissue interfere with migration of a drug in tumor, limiting its effect on the central region of the tumor, a potential source of tumor relapse and metastasis [106–108].

Drug delivery with NPs is more significantly influenced by this challenge because of the size and surface properties [105]. Goodman et al. predicted that movement of 100–200 nm NPs in tumor spheroids would be much restricted even with the treatment of an ECM-degrading enzyme [109]. It was also experimentally demonstrated that the intratumoral distribution of 60 nm polymeric micelles was limited and localized in proximity to the blood vessel [69]. The size restriction is particularly problematic in the treatment of tumors with hypovascular and hypopermeable properties such as pancreatic tumors [110]. In the case of NPs employing active targeting strategy, high affinity binding to the receptors can lead to the "binding site barrier effect" in solid tumors, where the NP–receptor interactions may prevent migration of NPs to the interior of tissues [2,69,111,112]. While an active targeting strategy has the potential to improve the delivery of drugs through the intracellular uptake of NPs, the effect may be limited to the periphery of tumors when the size and binding site barrier play a dominant role in intratumoral disposition of the NPs.

### 1.4.4 Regulatory Considerations

The unique properties of NPs enabled by the size and surface pose different safety issues than free drugs and larger dosage forms [113]. The U.S. Food and Drug

Administration's Nanotechnology Task Force, formed in August 2006, solicited the agency's action to develop a regulatory guidance for manufacturers and researchers [114]. However, much remains uncertain as to how their safety should be tested and how much time and cost will be required for the approval of NP products, especially those designed with multiple functionalities. Such uncertainties negatively influence the investors and development partners, when the new product brings about only mild improvement over existing products.

New drug products must pass the regulatory scrutiny that examines their safety, effectiveness, and potential hazards. Reproducibility and predictability of the product's performance are the most important quality criteria under any test methods and models. Accordingly, it is important to ensure that NPs have consistent properties, such as size, charge, shape, and density of surface functional groups. Increasing complexity of a formulation increases the difficulty of quality control as well as the development cost. Therefore, the current effort to develop new types of NPs must undergo a careful cost–benefit analysis prior to a significant investment.

## 1.5 FUTURE PERSPECTIVES

Several recent studies attempt to address the challenges discussed so far [105]. For example, Maeda et al. proposed the use of drugs that artificially augment the EPR effect [102]. Angiotensin II was used to elevate systemic blood pressure [115], and nitroglycerin or other agents inducing nitric oxide production were used to facilitate vascular blood flow and permeability [116]. These approaches have shown the potential to overcome the heterogeneity of the EPR effect. To overcome the limitations in NP distribution in tumors, ECM-degrading enzymes such as hyaluronidase and collagenase were proposed as a potential aid to reduce the stiffness of ECM and the interstitial fluid pressure [109,117]. While ongoing studies are likely to make these challenges under control, additional issues await future efforts. Here we discuss the remaining homework for the advancement of nanomedicine.

### 1.5.1 *In Vitro* Models

Preclinical studies of anticancer drugs and NPs are first carried out in cell culture models. The cell culture model is a convenient and inexpensive way of screening the effectiveness of a drug or an NP formulation. However, it is not unusual that these drugs and NPs showing great efficacy in cell culture models are often proven much less effective *in vivo*. The lack of predictability is due in part to the fact that a single cell population grown in a two-dimensional (2D) layer barely reflects the nature of human tumors, which involves an intricate cross talk between different cell populations and three-dimensional (3D) organization of cells and ECM [118]. There is an increasing understanding of the significance of 3D architecture of tumors, cell populations, matrix composition and mechanics, and the gradients of signaling materials in modeling tumors *in vitro*. Accordingly, active efforts are made to build

more realistic *in vitro* tumor models [119–121]. Lessons learned from tissue engineering and regenerative medicine are urgently solicited in these efforts.

### 1.5.2 *In Vivo* Models

Owing to the relatively low cost and well-established protocols, mouse models with allograft or human xenograft tumors are widely used in the evaluation of *in vivo* performance of NPs. In these models, cancer cells are inoculated (typically subcutaneously) in immunodeficient mice, allowed to grow into visually identifiable tumors, and treated with a new formulation to examine the pharmacokinetics, biodistribution, and pharmacological effects. However, several cases show that the results of preclinical studies are poorly correlated with Phase III outcomes. For example, in a preclinical study with mice bearing C-26 colon carcinoma, PEGylated liposomes carrying doxorubicin achieved significant survival benefits than free doxorubicin, attributable to their accumulation in tumors [122]. On the other hand, the PEGylated liposomal doxorubin was at best equivalent to free doxorubin in clinical efficacy (progression-free survival and overall survival) in a randomized Phase III trial with metastatic breast cancer patients [123]. In another example, a macromolecular conjugate of PTX and poly(L-glutamic acid) (PTX poliglumex) demonstrated a prolonged circulation half-life and greater tumor uptake and antitumor activity as compared to Taxol (PTX solubilized with Cremophor EL) at the same dose in a mouse model with syngeneic ovarian carcinoma [124]. However, the developer officially withdrew its application for a marketing authorization of PTX poliglumex for the first-line treatment of lung cancer patients because of the lack of therapeutic advantages over the comparators and unexplained toxicity [125].

In explaining the gap between the results of xenograft models and clinical outcomes, several limitations of current animal models may be considered [118,126]. First, the size and growth rate of tumors in mice are not comparable to those of human patients. Human patients with tumors large enough to detect with visual inspection would be candidates for surgical debulking rather than chemotherapy. Metastatic or microscopic residual tumors would be more appropriate subjects of targeted chemotherapy, but not much is known about the vasculature structure of those tumors and the effectiveness of the EPR effect. Second, since many animal models employ allografts or human tumor xenografts, the use of immunodeficient mice is inevitable. The potential consequences of immune responses to NPs are underrated in these models. Third, when human xenografts are inoculated in mouse models, the tumors recruit substances to build ECM from mice as they grow. The potential impact of this artificial arrangement on the architecture of ECM, cell–ECM interactions, and tumor propagation is barely considered in the interpretation of preclinical studies. Fourth, even though a xenograft can represent important attributes of the original tumors, it is uncertain whether it captures the genetic and epigenetic variability of tumors in its entirety [118].

When preclinical studies in animal models are essential steps providing the rationale for clinical trials, successful development of NP products depends critically

on the availability of reliable animal models. At this point, it is yet unclear what would be the best animal model for predicting clinical outcomes of a drug product. One potential alternative to the subcutaneous xenograft is an orthotopic model, where a xenograft grown in proximity to the tissues or organs from which the tumor cell line was derived [118]. This model has advantages over the subcutaneous model as it provides an environment closer to a normal milieu of the tumor. One may also envision that genetically modified animals will have a promise in recapitulating the progression of human tumors and increasing the predictability of clinical outcomes.

### 1.5.3 New Targets

Although the current state-of-the-art targeting strategies have largely relied on specific interactions between cell surface markers and ligands, a number of studies have also found that the efficacy demonstrated *in vitro* or *in vivo* model does not translate at the clinical level. This has partly to do with the fact that a tumor is not a collective mass of a single-cell population expressing a consistent level of markers at all times. To the contrary, a tumor is highly heterogeneous and dynamic both in composition and genetic makeup. This makes it difficult to achieve a consistent outcome with an NP targeting a single type of molecular target [60,91]. Targeting multiple markers simultaneously is a conceivable alternative to the current targeting strategy. In addition, quiescent cancer cells or tumor-initiating cells are suggested as a potential target of drug delivery [127]. The tumor-initiating cells or cancer stem cells (CSCs), a subpopulation of cancer cells similar to stem cells, are believed to differentiate into new tumors when specific conditions are met. CSCs are known to be resistant to current radio- and chemotherapy, and some believe that the surviving CSCs are partly responsible for metastasis and recurrence of the disease [127]. Potential targets for NP-based drug delivery to CSCs include cellular markers such as CD44 and CD133 and hypoxic conditions that lead to the formation of CSC niches [127].

### 1.5.4 New Therapeutic Agents

While NPs have contributed to reducing toxic side effects of traditional chemotherapeutic drugs [123,128], their accumulation (and side effects) in the RES and bystander organs is currently inevitable. NPs may be a more useful tool for the delivery of alternative therapeutic agents, which are inherently specific to tumor cells (thus benign to normal tissues) but unstable in circulation or do not have an effective means to access target cells. Nucleic acid therapeutics such as small-interfering RNA, microRNA, or antisense oligonucleotides have proven effective in suppressing intrinsic drug resistance and survival of cancer cells, but their delivery is challenging. Various NPs are currently developed for the systemic delivery of these gene therapeutics [129], and one of them has entered a Phase I clinical trial in 2008 [130].

## 2.1 INTRODUCTION

Over the past two decades, a variety of therapeutic modalities have been investigated for the treatment of cancer. Among the most promising new modalities in the field of medical applications is nanomedicine, which has proven to be an outstanding approach for improving therapeutic index [1,2]. Nanomedicines can achieve remarkable improvements in anticancer efficacy not only by increasing bioavailability and half-life, but also by promoting tumor-accumulation of therapeutic entities through the enhanced permeability and retention (EPR) effect [3]. Moreover, through modifications of the surface of nanoparticles, nanomedicines have showed the ability to improve target-specificity and further enhance the efficacy [4].

### 2.1.1 Nanoparticulate Drug Delivery

Nanoparticles are a proven modality for altering the *in vivo* fates of various therapeutic entities, such as small molecules, nucleic acids, and peptides [5]. Nanoparticulate drugs can achieve prolonged retention *in vivo*, increased accumulation in tumor tissues, and enhanced pharmacodynamics [1]. Depending on the materials used to construct them, nanoparticles are mainly classified as lipid- or

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*,

polymer-based. The series of nanomedicines on the market and in clinical trials substantiates the potential of nanoparticles as drug-delivery platforms [5,6]. Among nanomedicines, lipid-based nanomedicines, particularly liposomes, have a long history of commercialization. Following *in vivo* administration, the surface of liposomes easily interacts with serum proteins, promoting their elimination by the reticuloendothelial system. More prolonged circulation in the blood has been achieved by introducing poly(ethylene glycol) (PEG) moieties on liposomal surfaces, thereby reducing the interaction of liposomes with blood components. Such surface coating with PEG has been applied not only to liposomes but also to other nanoparticles. The current status of nanomedicines on the market is summarized in Table 2.1.

**TABLE 2.1 Current Status of Nanomedicine on the Market**

| Product Name | Active Drug | Company | Indications |
|---|---|---|---|
| *Lipid-based* | | | |
| Daunoxome | Daunorubicin | Nexstar | Kaposi's sarcoma |
| Myocet | Doxorubicin | Zeneus | Combinational therapy of recurrent breast cancer |
| Doxil/Caelyx | Doxorubicin | Tibotec | Refractory Kaposi's sarcoma |
| | Doxorubicin | ALZA | Ovarian cancer/recurrent breast cancer |
| DepoCyt | Cytarabine | Enzon | Lymphomatous meningitis |
| Onco TCS | Vincristine | Enzon/Inex | Non-Hodgkin's lymphoma |
| Ambisome | Amphotericin | Nexstar | Fungal infection in immunocompromised patients |
| Visudyne | Verteforfin | QLT/Norvatis | Wet age-related macular degeneration |
| Depo Dur | Morphine sulfate | Pacira Pharm | Postsurgical pain |
| *Polymer-based* | | | |
| Neulasta | PEG–GCSF | Amgen | Neutropenia associated with cancer chemotherapy |
| Pegasis | PEG–IFN2a | Genentech | Melanoma/Chronic myeloid leukemia/renal-cell carcinoma |
| Oncaspar | PEG–L-asparaginase | Enzon | Acute lymphoblastic leukemia |
| Zinostatin stimalamer | SMANCS | Yamanouchi | Hepatocellular carcinoma |
| Genexol-PM | Paclitaxel | Samyang | Metastatic breast cancer |
| *Others* | | | |
| Abaxane | Albumin-bound paclitaxel | Abraxis bioScience/ AstraZeneca | Metastatic breast cancer |

GCSF, granulocyte colony-stimulating factor; IFNα, interferon-α; SMANCS, styrene maleic anhydride neocarzinostatin.

### 2.1.2 Engineered Nanoparticulate Drug Delivery

Although nanoparticulate drugs have been equipped with attractive features such as improvements in pharmacokinetic and pharmacodynamic profiles, they still suffer from the lack of an active driving force for tissue or cell-specific delivery, relying instead on the EPR effect. Under *in vivo* conditions, nanoparticles confront formidable biological barriers that impede their delivery to target tissues, including the reticuloendothelial system, vascular endothelium, and blood enzymes [7]. Coating nanoparticle surfaces with PEG increases their stability in the bloodstream, but it does not enhance their interactions with specific types of tissues or cells. To the contrary, there have been reports that higher PEG content in nanomedicines can even reduce interactions of nanoparticles with cells [8]. Numerous approaches have been developed to overcome such limitations through modification of nanoparticles with various ligands, including antibodies, peptides and proteins, sugars and polysaccharides, and chemicals.

## 2.2 LIGAND-MEDIATED DELIVERY

### 2.2.1 Antibodies

Because of their specific antigen-recognition properties, antibodies have long been studied as a way of increasing the specificity of nanomedicine delivery [9,10]. The types of antibody variants considered for this purpose include single-chain variable fragments (scFv), $F(ab')_2$ fragments, and whole IgG antibodies. In cancer-related applications, targeting is typically achieved by tagging nanoparticles with antibodies against proteins known to be overexpressed on the surface of tumor cells relative to normal cells. Commonly studied cancer target proteins include HER2, selectins, and the epidermal growth factor receptor (EGFR). The primary methods for tagging antibodies to nanoparticles are covalent chemical conjugation and specific biomimetic interaction methods. *In vivo* applications of antibody-tagged nanomedicines are summarized in Table 2.2.

#### *2.2.1.1* In Vivo *Applications of Antibody-Tagged Nanomedicines*

*Nanoparticles Targeted to Tumors.* Taking advantage of the fact that HER2 is overexpressed on several cancer cells, researchers have tagged liposomes entrapping vincristine [11] or doxorubicin [12] with HER2-specific antibodies. Liposomes entrapping the anticancer drug vincristine were tagged with anti-HER2 antibodies by coupling to maleimide-modified PEG lipids [11]. Modification of vincristine liposomes with anti-HER2 antibody was shown to provide greater efficacy than free vincristine or unmodified liposomal vincristine against the HER2-overexpressing breast cancer cell lines, BT474-M2 and SKBR3. For *in vivo* applications, anti-HER2 antibody-modified immunoliposomes, unmodified liposomes, and free vincristine were intravenously administered to BT474-M2-xenografted mice at a dose of 1 mg/kg once a week for 3 weeks. Compared to other groups, immunoliposomes

**TABLE 2.2** ***In Vivo*** **Applications of Antibody-Tagged Nanomedicines**

| Target | Disease or Target Tissue | Nanoparticles | Active Substances | *In Vivo* Model | References |
|---|---|---|---|---|---|
| HER2 | Breast cancer | Liposome | Vincristine | BT474-M2-bearing mice | 11 |
| HER2 | Breast cancer | Liposome | Doxorubicin | MCF-7/HER2-bearing mice | 12 |
| C-met | Lung cancer | Liposome | Doxorubicin | H1993-bearing mice | 13 |
| BRCAA1 | Gastric cancer | $Fe_3O_4$ nanoparticles | Fluorescent magnetic nanoprobes | MGC803-bearing mice | 14 |
| EGFR | Glioblastoma multiforme | Liposome | Sodium borocaptate | EGFR-overexpressing U87-bearing mice | 16 |
| EGFR | Glioblastoma multiforme | Liposome | Fluorescent dye (8-hydroxypyrene–1,3,6-trisulfonic acid trisodium salt) | EGFR-overexpressing U87-bearing mice | 25 |
| EGFR | Hepatocellular carcinoma | Poly(lactic acid-*co*-L-lysine) nanoparticle | Fluorescent dye (rhodamine B) | SMMC7721-bearing mice | 17 |
| E-selectin | MCa-4 mammary tumor | Liposome | Combretastatin | MCa-4-bearning mice | 18 |
| THY 1.1 | Mesangial cells in kidney | Liposome | Doxorubicin | Wistar rats | 19 |

| LFA-1 | Human immunodeficiency virus-infected cells | Liposome | Anti-CCR5 siRNA | Humanized mice | 21 |

produced a greater reduction in tumor volumes and were well tolerated without causing substantial weight loss.

In addition to anti-HER2 antibody, quantum-dot (Q-dot) nanoparticles have been further conjugated to doxorubicin-loaded liposomes to create multifunctional imaging and therapeutic nanomedicines [12]. In this study, anti-HER2/ErbB2 scFv fragments were conjugated to one end of liposomal surface PEG, and carboxyl Q-dots were chemically tethered to the other end of liposomal surface PEG. *In vivo* imaging revealed a greater accumulation of anti-HER2 scFv- and Q-dot-conjugated doxorubicin immunoliposomes than Q-dot-conjugated liposomes in tumor tissues following intravenous administration in MCF-7/HER2-xenografted mice.

Anti-cMet scFv has been used to modify doxorubicin-loaded liposomes and Q-dot nanoparticles [13]. Doxorubicin-loaded liposomes were modified with anti-cMet scFv by coupling to maleimide-modified PEG chains on the external surface of liposomes. Anti-cMet scFv was similarly linked to maleimide-activated Q-dots. In H460-derived lung cancer xenografted mice, intravenous administration of 2 mg/kg of doxorubicin in an anti-cMet scFv-modified liposome formulation was shown to be almost twice as effective in reducing tumor volume as unmodified liposomes. Molecular imaging in mice revealed a greater distribution of anti-cMet scFv-modified Q-dots in tumors than unmodified Q-dots. However, a substantial distribution of Q-dots to tissues other than tumors was noted in the upper tail region, regardless of scFv modification. Such a distribution of Q-dots to the normal tail region may limit the targeted imaging of tumor tissues.

In addition to Q-dots, fluorescent magnetic nanoparticles have been conjugated with anti-BRCAA1 antibody to allow *in vivo* fluorescence and magnetic resonance imaging of gastric cancers [14]. In these applications, fluorescent magnetic nanoparticles were first functionalized with a carboxyl group and then conjugated with anti-BRCAA1 antibody using 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide and *N*-hydroxylsuccinimide as coupling agents. Treatment of the MGC803 gastric cancer cell line with anti-BRCAA1 antibody-tethered fluorescent magnetic nanoparticles provided a twofold increase in cellular-uptake efficiency compared to plain fluorescent magnetic nanoparticles. *In vivo* fluorescence imaging showed that the tumor tissue distribution of anti-BRCAA1 antibody-coupled nanoparticles in MGC803-xenografted mice peaked 6 h after intravenous administration. Magnetic resonance imaging obtained within 12 h after administration revealed a higher tumor distribution of anti-BRCAA1 antibody-coated magnetic nanoparticles compared to plain nanoparticles.

Antibodies against EGFR, which is overexpressed in malignant glioblastoma but weakly expressed or undetectable in normal brain [15], have been used for ligand modification of liposomes and polymeric nanoparticles. In particular, sodium borocaptate-loaded liposomes tagged with anti-EGFR antibody have been used for boron neutron capture therapy [16]. After intravenous administration of immunoliposomes to U87-EGFR cell-xenografted mice, the distribution of sodium borocaptate-loaded liposomes to the tumor tissues was tested by quantitation of boron compounds. Compared to unmodified liposomes, anti-EGFR antibody-tagged

liposomes delivered higher amounts of boron compounds to tumor tissues, but not to the normal brain, liver, or blood.

Poly(lactic acid-*co*-L-lysine) nanoparticles have been modified with anti-EGFR-antibodies [17]. For chemical tethering, these antibodies were linked to the surface of poly(lactic acid-*co*-L-lysine) nanoparticles using the coupling agents, 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide and *N*-hydroxylsuccinimide, and rhodamine B was loaded into the nanoparticles as a tracer of cellular uptake. In the SMMC-7721 hepatocellular carcinoma cell line, the internalization of anti-EGFR-antibody-conjugated poly(lactic acid-*co*-L-lysine) nanoparticles was decreased in the presence of excess amounts of free anti-EGFR antibodies, indicating that nanoparticles were endocytosed via EGFR receptors. In SMMC-7721-bearing mice, polymeric nanoparticles with or without anti-EGFR antibody were distributed to tumor tissues 4 h after intravenous administration, with anti-EGFR antibody-conjugated nanoparticles showing more prolonged retention within tumor tissues during the 48 h after dosing.

Modification of PEGylated liposomes with an anti-E-selectin antibody has been studied as a means to improve distribution to mammary tumor tissues [18]. In this application, an anti-E-selectin antibody was coupled to the distal end of maleimide (2 mol%)-functionalized PEG formulated in liposomes entrapping the antivascular drug, combretastatin A4 disodium phosphate (CA4DP). At equivalent doses (15 mg/kg), anti-E-selectin antibody-tagged liposomes incorporating CA4DP showed greater anticancer efficacy in mice bearing MCa-4 mammary tumor cell xenografts than plain liposomes incorporating CA4DP and was more efficacious than a higher dose (81 mg/kg) of free CA4DP. Moreover, when used in combination therapy, CA4DP chemotherapy using E-selectin antibody-tagged liposomes synergized with radiation therapy to produce greater anticancer effects than chemotherapy or radiation therapy alone.

*Nanoparticles Targeted to Other Diseases.* Although many antibody-modified nanomedicines have been studied for targeting tumor tissues, recent studies have reported applications of immunoliposomes for kidney diseases [19], vascular diseases [20], and antiviral therapy [21]. The therapeutic entities carried by these immunoliposomes include doxorubicin, cytokine proteins, and small interfering RNA (siRNA).

The $F(ab')_2$ fragment of an anti-OX7 antibody, which has an affinity for Thy 1.1 antigen on mesangial cells in the kidney, has been used to enhance the delivery of doxorubicin-loaded liposomes to rat kidney [19]. In this application, anti-OX7 $F(ab')_2$ was conjugated to the surfaces of liposomes via maleimide functionalized PEG lipids. Intravenously administered anti-OX7 $F(ab')_2$-conjugated liposomes were shown to specifically enhance delivery to mesangial cells in both kidneys. In contrast, free OX7 $F(ab)_2$ fragments coadministered with liposomes did not enhance renal delivery. Treatment of rats with low-dose doxorubicin (0.24 mg/kg) resulted in extensive glomerular damage in the case of immunoliposomes, whereas such treatment with unmodified liposomes or free drug did not. This study indicates the utility of immunoliposomes for treatment of renal diseases.

In myocardial infarction, ischemic myocardium sites are reported to exhibit upregulation of cell-adhesion molecules, such as P-selectin. On the basis of this pathology, an anti-P-selectin antibody was designed to target altered vascular endothelial surfaces [20]. In this study, anti-P-selectin antibody was conjugated to the maleimide group on the 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[(polyethylene glycol)2000] (DSPE–PEG2000) component of the liposome. Next, vascular endothelial growth factor was loaded into anti-P-selectin-conjugated liposomes by rehydrating freeze-dried immunoliposomes with vascular endothelial growth factor (VEGF) solutions. In the rat myocardial infarction model, treatment with VEGF-loaded immunoliposomes was reported to significantly improve cardiac function and the number of perfused vessels compared to controls [20].

For siRNA-based antiviral therapy, liposomes have been modified with an antibody against lymphocyte function-associated antigen-1 (LFA-1) [21]. In this approach, rather than using PEG as a stabilizing moiety, hyaluronan 751 kDa was used as a liposome-surface modifier to increase stability in the bloodstream. Hyaluronan-modified liposomes were then conjugated with anti-LFA-1 antibody using an amine-coupling method. CCR5-specific siRNA was entrapped by rehydrating lyophilized liposomes with CCR5-specific siRNA and a protamine complex solution. The resulting immunoliposomal siRNA was injected into humanized mice via the tail vein at a dose of 50 μg/mouse. Subsequent challenge of humanized mice with human immunodeficiency virus was shown to provide enhanced resistance to infection by reducing viral load.

#### *2.2.1.2 Methods for Tagging Nanomedicines with Antibodies*

*Covalent Conjugation.* Because antibodies must retain their three-dimensional conformation to specifically interact with antigen epitopes, methods used to tag nanomedicines with antibodies should be carefully controlled. Although new methods of antibody tagging have been developed, the most widely used method has been the chemical conjugation method, where the antibody is linked to activated groups on the surfaces of nanoparticles via covalent bonding [22].

Maleimide groups have been used to provide activated ends to nanoparticles, allowing conjugation to sulfhydryl groups in cysteine residues of the antibody. This method has been used to modify drug-entrapped liposomes with various antibodies, including the anti-cMet scFv [13], and anti-OX7 $F(ab')_2$ fragments [19], and anti-HER2 [11], anti-E-selectin [18], and anti-P-selectin [20] antibodies, described earlier.

Alternatively, the surface of nanoparticles can be chemically modified using 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide and *N*-hydroxylsuccinimide as coupling agents. Examples of this include the modification of poly(lactic acid-*co*-L-lysine) nanoparticles with anti-EGFR-antibody [17] and modification of fluorescent magnetic nanoparticles with anti-BRCAA1 antibody [14].

Chemical coupling methods, however, suffer from several potential limitations. First, chemical coupling may affect the three-dimensional conformation of antibodies. Second, antibodies bound by nonspecific coupling are randomly oriented.

Both altered conformation and random orientation may result in the loss of antibody activity. Moreover, tagging antibodies to nanoparticles through complex reaction procedures requires time and effort.

*Noncovalent Binding.* To overcome the limitations inherent in chemical coupling methods, researchers have developed noncovalent biomimetic linking methods based on specific interactions. The prototypical example of this is based on protein A, a protein produced by *Staphylococcus aureus* that binds to the Fc domain of antibodies through its ZZ motif. Protein A has been exploited to prevent opsonization in the bloodstream [23] and has been applied to biotechnology products for the separation of antibodies from protein mixtures and the design of protein chips [24]. In the current context, the antibody-affinity ZZ motif of protein A has been used to tag antibodies to the surface of liposomes without chemical coupling. In a previous study by Feng and colleagues, a ZZ-His peptide was first bound to the nickel component of Ni lipid-containing liposomes through Ni–His interactions [16]. The resulting liposomal surface ZZ was used to tag an anti-EGFR antibody by simply mixing at room temperature. This approach, however, is limited by the potential cytotoxicity of the liposomal Ni used for His binding. Moreover, directly tagging an antibody to the surface of liposomes with PEG lipid chains may reduce the probability of antibody interaction because of steric hindrance of neighboring PEG chains.

In a more recent study, Feng and colleagues sought to improve the ability of antibodies to recognize and bind to target cells by designing liposomes that positioned the antibody further out from the liposome surface than did the Ni liposomes used previously. To accomplish this, they first modified maleimide-functionalized PEG chains of liposomes with a thiolated form of Gaussia luciferase-ZZ-His [25]. Gaussia luciferase is a 19.9 kDa bioluminescent reporter protein that provides an imaging functionality. Anti-EGFR antibodies were then bound to the ZZ domain at the distal end of PEG chains on the liposomal surface. The presence of Gaussia luciferase enabled monitoring of the *in vivo* fate of immunoliposomes by bioluminescence imaging.

In addition to the ZZ motif, a cyclic 13-mer peptide has been reported to be a crucial sequence for the Fc-binding function of protein A [26]. Taking advantage of the Fc-binding 13-mer peptide (FcBP), Oh and colleagues linked the peptide to functionalized PEG lipid derivatives [27], and then used the FcBP-linked PEG lipids to formulate liposomes to which antibodies could be bound via the specific affinity of FcBP. Subsequent attachment of anti-CXCR4 antibody to FcBP-modified liposomes resulted in enhanced cellular uptake by a CXCR4-positive Ramos cell line compared to plain liposomes.

Compared with the conventional chemical conjugation methods (Figure 2.1a), protein A-based affinity methods for noncovalently tagging antibodies (Figure 2.1b) may have advantages in retaining the three-dimensional conformation of liposomes and controlling the orientation of antibodies. However, this Fc moiety affinity-based approach is also limited in that it cannot be used to coat liposomes with scFv or $F(ab')_2$ fragment type antibodies, which lack in the Fc portion.

**FIGURE 2.1** Covalent and noncovalent antibody-tagging methods. (a) Covalent tagging of antibody to the distal end of maleimide-functionalized PEG derivative of lipid. (b) FcBP-based noncovalent and specific tagging of antibody to a PEG derivative of lipid.

### 2.2.2 Peptides and Proteins

Compared to the variety of antibodies that can confer specific binding to overexpressed antigens on pathogenic cells, the menu of proteins and peptide ligands available for modification of nanoparticles is limited. With the exception of the widely studied transferrin, few proteins have been used for modifying nanoparticles. Peptide ligands have been more actively studied owing to the recent development of phage-display technologies, which allow for discovery of new peptides with high affinity for specific targets. Compared to protein ligands, peptide ligands are advantageous in that they can be easily synthesized and are thus commercially available. Moreover, their relatively small size makes it easy to handle in chemical

coupling methods. For example, functional amino acids can be added synthetically near each terminal of peptides, providing control over coupling sites and reaction methods.

***2.2.2.1 Transferrin.*** The iron-binding protein transferrin has been widely studied for modifying anticancer drug-loaded nanomedicines owing to the high expression of transferrin receptors on various cancer cells [28,29]. Iron-bound transferrin specifically interacts with transferrin receptors, resulting in receptor-mediated endocytosis and delivery of iron into cells [30]. The expression levels of transferrin receptors are reported to be relatively high in rapidly proliferating cells, such as epithelial cells and cancer cells, compared to normal cells. Cancers known to express high levels of transferrin receptors include lung adenocarcinoma, breast cancer, chronic lymphocytic leukemia, and brain tumors [31]. The use of transferrin modification for enhancing the delivery of anticancer drugs to tumor tissues has been reported for various nanoparticles, including liposomes [32,33], polymeric nanoparticles [34–36], albumin nanoparticles [37], and gold nanoparticles [38].

Transferrin modification of doxorubicin-loaded stealth liposomes was shown to enhance cellular delivery of doxorubicin to HepG2 cells compared to unmodified, plain doxorubicin liposomes [32]. In this application, transferrin was linked to the surfaces of liposomes using 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide and *N*-hydroxylsuccinimide as coupling agents. Following intravenous administration in rats at a dose of 5 mg/kg, the pharmacokinetics of transferrin-modified liposomal doxorubicin was not substantially different from those of unmodified liposomal doxorubicin. Notably, despite the similar pharmacokinetics, intravenously administered transferrin-modified doxorubicin showed a greater distribution to tumor tissues in HepG2 cell-bearing mice, with peak accumulation occurring 24 h after administration. The similar pharmacokinetics in rats but enhanced anticancer effects observed for transferrin-modified doxorubicin liposomes reflect enhanced tumor tissue distribution and cellular uptake.

Transferrin-modified liposomes have been studied as a delivery system for an antisense oligonucleotide [33]. In this application, G3139, an antisense oligonucleotide targeting Bcl-2, was complexed with a mixture of liposomes and protamines to yield lipoplexes, after which transferrin-conjugated PEG lipids were inserted into the lipoplexes. Thirty-six hours after intravenous administration of G3139 (5 mg/kg) in K562-bearing xenografted mice, tumor uptake of transferrin-modified lipoplexes was higher than that of the free form of G3139. Because there was no comparison between transferrin-modified liposomes and plain liposomes in this study, it is difficult to conclude that the observed increase in tumor uptake was due to transferrin, given the EPR effect noted for nanoparticles.

In addition to liposomes, various polymeric nanoparticles have been modified with transferrin. For example, biodegradable poly(DL-lactide-*co*-glycolide) (PLGA) nanoparticles have been loaded with paclitaxel and modified with transferrin [35]. The surface of paclitaxel-loaded PLGA nanoparticles was epoxy activated and reacted with transferrin. A pharmacokinetic study of paclitaxel (20 mg/kg) in Sprague–Dawley rats

showed that the mean residence time of paclitaxel delivered by plain PLGA nanoparticles and transferrin-modified PLGA increased by 2.68 and 3.76 folds, respectively, as compared to a free paclitaxel solution. The distribution of paclitaxel to tumor tissues was highest with transferrin-modified PLGA, reaching a peak accumulation 2 h after intravenous administration.

Polycyanoacrylate nanoparticles carrying PEG-hydroxycamptothecin have also been modified with transferrin [39]. In normal Wistar rats, the pharmacokinetic profile of hydroxycamptothecin delivered in transferrin-modified PEG nanoparticles did not substantially differ from that in unmodified PEG nanoparticles. A fit to a two-compartment model showed that the elimination half-life of free PEG-hydroxycamptothecin was 0.68 h, but unmodified PEG nanoparticles and transferrin-modified PEG nanoparticles increased the half-life to 23.21 and 20.92 h, respectively. The tumor distribution of transferrin-modified PEG nanoparticles in S180 tumor-bearing mice, measured as area under the curve, was 2.12-fold higher than that of unmodified PEG nanoparticles, and reached a peak accumulation 4 h after intravenous administration.

Doxorubicin-loaded human serum albumin nanoparticles have recently been dual-modified with transferrin and tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) [37]. Dual labeling with transferrin and TRAIL was reported to enable the delivery of nanoparticles to multiple tumor types, including HCT 116 and CAPAN-1 cells, and drug-resistant MCF-7/ADR cells. Moreover, dual-ligand modification with transferrin and TRAIL was shown to provide synergistic tumor cell-killing activity, reflecting the cytotoxicity of doxorubicin and the induction of apoptosis via the TRAIL ligand. Transferrin/TRAIL-modified doxorubicin nanoparticles intravenously administered in HCT116-xenografted mice showed accumulation in tumor tissues, reaching a peak 16 h after injection.

One concern regarding transferrin-mediated delivery is rapid intracellular trafficking kinetics [30]. After receptor-mediated endocytosis, transferrin receptor/transferrin complexes release iron in the endosome and then rapidly recycle back to the cell surface. The short residence time of transferrin receptor-containing endosomes within cells may reduce the ability of transferrin to deliver the drugs entrapped in nanomedicines. One approach to improving the efficacy of transferrin-modified nanomedicines is genetically engineering variants of transferrin with decreased iron release rates [40]. This study tested genetic variants of transferrin in the context of a transferrin-conjugated cytotoxin, but this approach may be applicable to other transferrin-modified nanomedicines.

***2.2.2.2 Arginine–Glycine–Aspartic Acid (RGD).*** Integrins are among the most widely studied receptors for the tumor-targeted delivery of nanomedicines. Integrins, composed of a heterodimer of α- and β-subunits, play a role in such cellular functions as cellular adhesion, migration, and proliferation [41]. Of several types of integrins, integrin isoforms αυβ3, α5β1, and αυβ6 are overexpressed in various tumor tissues [42] and are thus attractive targets for cancer therapy. Integrins αυβ3 and αυβ5 have been well studied for cancer targeting since they are overexpressed not only in tumor cells but also in angiogenic endothelial cells [43].

The tripeptide, arginine–glycine–aspartic acid (RGD), is a part of certain extracellular proteins such as fibronectin and vitronectin that interact with integrins. This integrin-binding ligand has been used to modify the surfaces of nanoparticles carrying anticancer drugs. Since Pierschbacher and Ruoslahti first reported that RGD was involved in cell attachment [44], many groups have studied RGD for integrin-directed delivery of nanomedicines. Cyclic RGD is preferred to linear RGD because linear RGD has poor binding affinity for integrins [45]. Cyclic RGD has been linked to polymeric nanoparticles [46], dendrimers [47,48], and liposomes [49,50].

The cyclic pentapeptide RGDyK has been co-conjugated to PEGylated polyamidoamine dendrimers with the anticancer drug doxorubicin for targeting to tumor neovascular endothelial cells and tumor tissues [47]. In this application, doxorubicin was conjugated via an acid-sensitive *cis*-aconityl linkage to allow the release of free doxorubicin in the acidic endosomal compartment after endocytosis. The cyclic RGDyK pentapeptide was then linked using bifunctional *N*-hydroxysulfosuccinimide-polyoxyethylene-maleimide. Although no quantitative biodistribution data were provided, tumor sections were immunofluorescence-stained using an antivascular endothelial cadherin antibody to monitor the extent of tumor growth. Immunofluorescence staining revealed that vascular endothelial cadherin levels and, thus, tumor size were lowest in tumor tissues treated with cyclic RGDyK pentapeptide-linked conjugates.

In a recent study by the same group, cyclic RGD-linked PEGylated polyamidoamine dendrimers were conjugated with doxorubicin using an acid-insensitive succinic linkage or acid-sensitive aconityl linkage [48]. Quantitative biodistribution data showed that tumor accumulation of cyclic RGD–polymer conjugates with doxorubicin attached through an acid-sensitive aconityl linkage was twofold lower than that with doxorubicin attached through an acid-insensitive succinic linkage. Despite the lower tumor accumulation, cyclic RGD–polymer conjugates with doxorubicin attached via an acid-sensitive aconityl linkage promoted the longest survival times in mice. The prolonged survival effect is attributed to the acid-labile release of doxorubicin in endolysosomes following uptake of the conjugates by the tumor cells. Unlike acid-insensitive linkage, acid-sensitive linkage may facilitate the liberation of free doxorubicin from the conjugates and increase the diffusion of the liberated doxorubicin from acidic lysosomes to the cytoplasm and subsequently to the nucleus in an actively intercalating form. This study highlights the importance of free drug release at tumor sites, especially within intracellular environments.

Polycationic liposomes have also been modified with a cyclic RGD–PEG lipid derivative for systemic delivery of siRNA [49]. In this application the cationic charges of liposomes for electrostatic complexation with negatively charged siRNA were provided by dicetylphosphate-tetraethylenepentamine. The cyclic RGD modification was introduced into liposomes using a PEG lipid derivative of cyclic RGD in the liposome preparation. After intravenous administration into C57BL/6 mice bearing luciferase-expressing B16F10-luc2 cells, cyclic RGD–PEG polycationic liposomes containing luciferase siRNA produced the greatest degree of luciferase knockdown in B16F10 metastatic lung tissues [49].

Although most RGD-modified nanomedicines have been developed for the purpose of tumor-targeted delivery, other *in vivo* applications have been reported based on the high expression of αυβ3 integrins on angiogenic vascular endothelial cells. For example, instead of anticancer drugs, the anti-inflammatory drug dexamethasone phosphate has been loaded into RGD–PEGylated liposomes and tested in a rat arthritis model [50]. In this study, the authors observed an antiarthritic effect of the dexamethasone phosphate loaded RGD–PEGylated liposomes.

***2.2.2.3 Bombesin.*** Bombesin is a 14-amino-acid peptide with a high affinity for the gastrin-releasing peptide receptor, also called the bombesin receptor, which is highly expressed on the surface of prostate, breast, and small-cell lung carcinoma cells. Exploiting this overexpression of bombesin receptors, researchers have modified nanoparticles with bombesin peptide for tumor targeting and demonstrated enhanced delivery via bombesin receptors *in vitro* [51,52]. Bombesin-functionalized gold nanoparticles have also been designed as a delivery system for X-ray contrast agents for molecular computed tomography imaging of prostate tumors in mice [53].

***2.2.2.4 Other Peptides.*** Peptides that can distinguish between tumor and normal tissues are attractive in the development of cancer diagnostics and targeted-delivery systems for anticancer agents. The *in vivo* applications of other peptide-modified nanomedicines are summarized in Table 2.3. Peptides can be used as antibody replacements for modification of nanomedicines if the corresponding peptide-binding receptors are clearly identified [54]. The phage display technique has contributed greatly to the discovery of numerous potent peptides that bind to specific tumor cells with high affinity. However, phage display-derived peptides are limited by the lack of understanding of their cognate receptors. The development of techniques that allow the identification of specific receptors for peptides is needed for the advancement of this field.

### 2.2.3 Sugars and Polysaccharides

***2.2.3.1 Galactose.*** Galactose, a simple type of sugar, is a primary metabolic energy source for humans. Apart from the oral absorption of galactose in nutrients such as sugar beets, gum, and milk products, this monosaccharide is biochemically synthesized in the body as glucoproteins and glycolipids. In the nanomedicine field, galactose has been utilized for liver-targeted delivery because galactose-bearing asialoglycoproteins can bind the asialoglycoprotein receptors localized to parenchymal liver cells (i.e., hepatocytes) [64]. Thus, it is possible to target nanoparticles to liver cells and liver-derived cells by tethering galactose molecules to the nanoparticle surface.

Galactosylated multimodular lipoplexes have been studied as a means to deliver plasmid DNA into primary hepatocytes [65]. Galactosylated cationic vectors, including lipids and polyethyleneimines, have been shown to increase the efficiency of nucleic acid transfection into hepatocytes compared with the vectors lacking galactose. On the other hand, it is possible that the galactosylated cationic

nanoparticles might also have promoted nonspecific cellular uptake and cytotoxicity due to their positive charges. To reduce nonspecific cellular delivery, Letrou-Bonneval and colleagues developed multimodular assemblies with a guanidinium-cholesterol-based cationic liposomes core, which contained internally condensed plasmid DNA and external PEG with galactose at distal ends as a steric stabilizer. These colloidally stabilized, galactosylated lipoplexes were shown to increase the transfection efficiency of plasmid DNA in primary hepatocytes of Sprague–Dawley rats, whereas ungalactosylated lipoplexes did not.

*N*-Acetylgalactosamine, an amino sugar derivative of galactose, has also been used to target asialoglycoprotein receptors, specifically for receptor-targeted delivery of siRNA-carrying lipid nanoparticles [66]. To ascertain the role of *N*-acetylgalactosamine and asialoglycoprotein receptor interaction in the liver delivery of siRNA, these researchers intravenously administered factor VII-specific siRNA-loaded ionizable lipid nanoparticles containing various molar amounts of *N*-acetylgalactosamine-modified lipids to apolipoprotein $E^{-/-}$ mice at an siRNA dose of 0.2 mg/kg. A maximal gene-silencing effect in serum was observed at 0.15 mol% *N*-acetylgalactosamine moiety, indicating the importance of exogenous galactose modification of nanoparticles [66].

***2.2.3.2 Mannose and Its Derivatives.*** Mannose, a sugar monomer of a hexose, has several important biological roles, including the glycosylation of proteins. Unlike galactose interactions with asialoglycoprotein receptors on parenchymal liver cells, D-mannose is recognized by a mannose receptor generally present on nonparenchymal liver cells, such as Kupffer cells, macrophages resident in the liver.

Mannosylated liposomes have been studied for targeted delivery to alveolar macrophages [67]. Liposomes containing 9.1 mol% of mannosylation exhibited the most efficient uptake by alveolar macrophages *in vitro*. Tests showed that [$^3$H] cholesteryl hexadecyl ether-labeled mannosylated liposomes administered by pulmonary aerosolization in Sprague–Dawley rats accumulated in alveolar macrophages, with a peak level 2.5-fold greater than that observed with plain liposomes occurring 2 h after administration.

Mannose as a targeting moiety has also been used to modify ultrasound-responsive bubble liposomes for gene delivery [68]. Complexes of such mannose-modified liposomes with plasmid DNA have demonstrated mannose receptor-expressing cell-specific gene transfer *in vivo*. In the conventional lipoplex form of plasmid DNA delivery, endosomal trafficking of lipoplexes induced the production of tumor necrosis factor-α through recognition of plasmid DNA by endosomal toll-like receptor 9. It was expected that ultrasound stimulation would allow the delivery of lipoplexes directly into the cytoplasm, reducing the likelihood of DNA recognition by tumor necrosis factor-α. As predicted, exposure to ultrasound following intravenous administration of mannose-modified bubble liposomes to mice was shown to significantly reduce toll-like receptor 9 production in the exposed tissue [69].

Mannan, a mannose-containing polysaccharide recognized by the mannose receptor of antigen-presenting cells, has been used to coat superparamagnetic

iron oxide nanoparticles and applied to imaging of lymph nodes [70]. Mannan-coated superparamagnetic iron oxide nanoparticles injected into mice were shown to distribute to the lymph node to a greater degree than dextran-coated or poly(vinyl alcohol)-coated iron oxide nanoparticles. The accumulation of mannan-coated superparamagnetic iron oxide nanoparticles in the lymph node peaked after 1 h and gradually decreased until 24 h. Unlike mannan-coated nanoparticles, poly(vinyl alcohol)-coated iron oxide nanoparticles were mainly distributed in the spleen.

Mannose-6-phosphate has been used to modify human serum albumin for targeted delivery to cells expressing the mannose-6-phosphate/insulin-like growth factor-II receptor [71]. Such conjugates demonstrated an affinity for insulin-like growth factor-II receptor expressing B16 melanoma cells and were internalized by them. Two hour after intravenous injection into B16 bearing C57BL/6 mice, $^{125}$I-doxorubin-linked conjugates were mainly distributed in the liver (50% of injected dose), followed by the lung, kidney, stomach, small intestine, and tumor. A total of 3% of the injected dose of $^{125}$I-doxorubin-linked conjugates was distributed in tumor tissues, an amount less than 1/10 that in the liver. A particularly valuable aspect of this study is its quantitative presentation of biodistribution data as percentage of injected dose in 20 organs and tissues. Although the terminology "tumor targeting" is commonly used, the absolute percentage of distribution to the tumors as reported in this study suggests that the nanoparticles distribute in other tissues of the body to substantial extents.

***2.2.3.3 Hyaluronic Acid.*** Hyaluronic acid, an anionic glycosaminoglycan, is a carbohydrate abundant in the body. Notably, it is a major component of the extracellular matrix, which participates in cell proliferation, migration, and interaction with cell surface receptors, including intracellular adhesion molecule-1 and CD44, the receptor for hyaluronic acid-mediated motility [72,73].

Reducible polyethyleneimine-grafted hyaluronic acid has been synthesized and used for systemic delivery of siRNA against liver cirrhosis [74]. Systemic administration of apolipoprotein B-specific siRNA using reducible polyethyleneimine-grafted hyaluronic acid complexes was shown to reduce target gene expression and increase therapeutic efficacy in a mouse model of liver cirrhosis.

In liver fibrosis, the expression of matrix metalloproteinases is imbalanced; thus, one therapeutic strategy is to restore metalloproteinase activity by delivering plasmid DNA encoding matrix metalloproteinases. To this end, hyaluronic acid, which is negatively charged, can be used to form electrostatic triple complexes with preformed dual complexes of plasmid DNA encoding matrix metalloproteinase 13 and polyethyleneimine [75]. The resulting DNA–polyethyleneimine is shielded with hyaluronic acid by charge interactions. Intravenous administration of the hyaluronic acid-shielded plasmid DNA complexes into mice was shown to ameliorate the progression of liver fibrosis as evidenced by a reduction in collagen deposition. In this study, the shielding with hyaluronic acid was shown to reduce the toxicity of the polyethyleneimine vector. Without hyaluronic acid shielding, the maximum dose of plasmid DNA that could be systemically administered was 1 mg/kg, owing to the toxicity of polyethyleneimine. However, the shielding of

hyaluronic acid reduced the toxicity of polyethyleneimine, allowing 100% survival of mice at a plasmid DNA dose of at least 3 mg/kg.

In a recent study, hyaluronic acid itself was used as nanoparticle material for anticancer drug delivery [76]. Hyaluronic acid is biodegraded by the endogenous enzyme hyaluronidase, which is known to be particularly abundant in malignant tissues and metastatic cancers. To exploit this abundance of hyaluronidase and facilitate rapid release of drug at tumor sites, researchers have formulated PEG-conjugated hyaluronic acid nanoparticles loaded with an anticancer drug, camptothecin. Studies of the biodistribution of camptothecin-loaded PEGylated hyaluronic acid nanoparticles showed tumor localization in mice bearing CD44-expressing tumors. Camptothecin-loaded PEGylated hyaluronic acid nanoparticles prevented significant increases in tumor size for at least 35 days.

### 2.2.4 Small Molecule Chemicals

***2.2.4.1 Folate.*** Folate—water soluble Vitamin $B_9$—plays several roles in biosynthesis, including nucleic acid metabolism (e.g., DNA and RNA synthesis), prevention of DNA changes, and amino acid production. Notably, folate is required for the replication of DNA during cell division and proliferation. Cancer cells, which grow very rapidly, express high surface levels of folate receptors, which mediate cellular uptake of folate. Given the higher relative expression of folate receptors on tumor cells, it is not surprising that folate has been widely studied as a ligand molecule for nanomedicines carrying anticancer drugs or imaging agents [77,78]. *In vivo* applications of folate-modified nanomedicines are summarized in Table 2.4.

In the study of Yamada and colleagues [79], different *in vitro* and *in vivo* results were observed between doxorubicin in free form and folate-modified liposomes. *In vitro*, free doxorubicin showed higher antitumor activity than doxorubicin in folate-modified liposomes. In folate receptor-expressing KB cells, the concentration leading to 50% of cell death was 0.65 and 1.27 μg/ml for doxorubicin in free form and in liposomes with folate linked to the distal end of PEG lipid chain (mw 5000), respectively. In contrast, *in vivo* antitumor activity of doxorubicin was found to be higher in folate-liposomes as compared to free form. This difference was explained by the different *in vivo* distribution pattern of doxorubicin. The distribution of doxorubicin to tumor tissues was found only in the mice intravenously injected with folate-modified liposomes but not in the mice treated with free doxorubicin.

The importance of drug release at the target site has motivated development of an approach that controls the release of drug in a pH-responsive manner. Here, folate has been linked to pH-sensitive polymeric micelles composed of PEG–poly (aspartate–hydrazone–doxorubicin) for tumor tissue delivery of doxorubicin [80]. In this application, the anticancer drug doxorubicin was conjugated to pH-sensitive hydrazone to facilitate the drug release in acidic intracellular compartments, such as lysosomes and endosomes, where pH ranges from 5 to 6. Conjugation of folate to pH-sensitive micelles dramatically increased cellular uptake and cytotoxicity *in vitro* compared to unmodified micelles. However, an *in vivo* distribution study revealed doxorubicin accumulation in tumors after delivery using micelles was similar with or

without folate modification. Despite the similar tumor accumulation, folate-conjugated micelles showed lower *in vivo* toxicity and a reduced effective dose, increasing the therapeutic window by fivefold compared to the free drug. The absence of a difference in tumor accumulation between micelles with and without folate conjugation was explained by the dominance of the EPR effect in determining the tumor accumulation of drug carriers. The higher therapeutic window of folate-modified micelles indicates that folate conjugation may affect the tumor distribution of micelles after extravasation, rather than the migration of micelles from the bloodstream into the tumor tissues.

Consistent with the results observed in this micelle study, another group reported no difference in the tumor tissue accumulation of a folate-modified nanomedicine [81]. Specifically, molecular imaging revealed that the tumor tissue distribution of heparin-paclitaxel nanoparticles modified with folate ligands was similar to that of unmodified particles. To determine whether nanoparticles simply accumulated outside tumor cells or actually entered them, these researchers stained tumor cells in the tumor tissues with an antihuman CD326 antibody. This tumor cell-identification strategy revealed that folate-modified nanoparticles were predominantly taken up by tumor cells, whereas unmodified nanoparticles were present in the extracellular space. Moreover, tumor volume was found to be significantly smaller in the

group treated with folate-modified nanoparticles compared to groups treated with unmodified nanoparticles or free drug. This increase in the *in vivo* anticancer efficacy of folate-modified nanoparticles suggests tumor-cell targeting after extravasation.

***2.2.4.2 Alendronate.*** Although small molecule chemical ligands have many advantages such as lower immunogenicity, ease of handling in modification processes, and possibly lower costs, only a few small molecule chemical ligands other than folate have been studied.

Alendronate, a drug used to prevent and treat osteoporosis, has been studied as a bone-targeting moiety in a mouse model of bone metastasis [92]. In this application, alendronate was linked to an *N*-(2-hydroxypropyl) methacrylamide-paclitaxel conjugate. An *in vivo* study showed that the alendronate-linked conjugate-treated group achieved greater tumor regression than did groups treated with free paclitaxel or a mixture of free paclitaxel and alendronate. Moreover, the alendronate-linked conjugate showed less hemolytic activity than Cremophor EL, a commercial vehicle for paclitaxel. Although the authors speculated that the higher efficacy and safety of alendronate-linked conjugate was due to a more favorable pharmacokinetic profile of the conjugate, quantitative data on tumor tissue distribution were not provided in this study.

***2.2.4.3 Anisamide.*** Sigma receptors are membrane-bound proteins with a high affinity for neuroleptics. Although sigma receptors are expressed on normal tissues, including liver, lungs, kidneys, and central nervous system, they are known to be overexpressed in diverse tumors. Huang and colleagues tested liposomes modified with the sigma receptor-binding ligand, anisamide, first studying anisamide-modified liposomes as delivery vehicles for doxorubicin [93]. A PEG-conjugated phospholipid was derivatized with an anisamide ligand, which was then incorporated into the doxorubicin-loaded liposome. *In vivo* imaging revealed that anisamide-conjugated liposomal doxorubicin showed significantly improved accumulation in the tumor.

In a recent study by the same group, anisamide-modified cationic liposomes were studied for systemic delivery of c-Myc-specific siRNA [94]. Four hours after intravenous administration to B16F10 melanoma tumor-bearing mice, anisamide-modified liposomes showed increased accumulation in tumors compared to unmodified liposomes. Western blots of tumor tissues showed that the c-Myc protein was silenced in the group treated with anisamide-modified liposomes, but not in other groups.

## 2.3 CURRENT CHALLENGES IN CLINICAL DEVELOPMENT OF LIGAND-MODIFIED NANOMEDICINE

### 2.3.1 Nonclinical and Clinical Studies

In addition to the *in vivo* case studies highlighted earlier, numerous animal studies are ongoing. Despite these efforts, very few powerful ligand-modified nanomedicine candidates have entered clinical trials. One such case is the transferrin-conjugated

immunotoxin, TransMid (Xenova Biomedix Co.), which has entered clinical trials as a locally administered treatment for brain tumors [95]. In this conjugate, transferrin is bound to diphtheria toxin through a lysine linker and a thioether. After binding to glioma cells, the conjugate enters the cells via receptor-mediated endocytosis and releases toxin, which kills the cells. This immunotoxin completed Phase I and II clinical trials, but was stopped during Phase III trials in late 2006 by the sponsor, Xenova Biomedix, according to a conditional power analysis showing that the conjugate would not significantly improve upon standard treatments for high-grade brain tumors.

A second case, EC-145, is under development by Endocyte Inc. [96], although putting this chemical drug conjugate in the category of nanomedicine may be arguable. EC-145 is a conjugate of folate and vinka alkaloid, in which folate is linked to the anticancer agent desacetylvinblastine monohydrazide through a peptide spacer. After promising preclinical trial results [97], the conjugate is currently in Phase II clinical trials in patients with advanced ovarian cancer.

One other nanomedicine undergoing clinical testing is Calando Pharmaceutical's nanomaterial, denoted CALAA-01, which is now in Phase I clinical trials [5,98] after completion of multi-dosing tests in nonhuman primates [99,100]. CALAA-01 consists of a human transferrin-tagged cyclodextrin-based polymer for systemic administration of siRNA against the M2 subunit of ribonucleotide reductase. Researchers at Calando have reported that systemic delivery of siRNA-loaded nanoparticles significantly reduced target gene expression in patients. Because CALAA-01 is not only a targeted nanoparticle but also an siRNA therapeutic, this first clinical trial for the treatment of solid cancer represents a significant step for the field of nanomedicine. It is worthwhile to note that the focus of the study in question was on the systemic administration of RNAi therapeutics rather than on the targeting ligand, and comparative studies of siRNA-loaded nanoparticles with and without transferrin are lacking. It remains to be seen whether the transferrin ligand played a vital role in the results of the clinical study.

### 2.3.2 Challenges and Future Perspectives

Numerous ligand-modified nanomedicine candidates have shown promise *in vitro*, but there are multiple *in vivo* barriers that can nullify the targeting capabilities of nanoparticles. One of the biggest barriers against the delivery to target tissues is the massive uptake of nanoparticles in the reticuloendothelial systems such as liver. As quantitatively reported in the study using mannose-6-phosphate as a targeting moiety [71], described earlier, 50% of the injected dose was found in the liver, with less than 5% of the dose reaching the tumor tissue. To increase the delivery to tumors or other target sites, it is essential that the substantial distribution of nanoparticles to the liver be decreased.

One approach for reducing such off-target delivery is to increase the selectivity of the nanomedicine. To date, most nanomedicines have been modified with a single ligand whose receptors are overexpressed on target cells. However, it is practically not easy to identify suitable receptors that exist exclusively on target cells. As a

result, off-target binding of nanomedicines to other normal cells that also express the same receptor is unavoidable. To circumvent this limitation and increase the selectivity for tumor cells, which actually overexpress multiple types of surface receptors, Saul and coworkers have recently suggested a dual-ligand approach [101]. In their *in vitro* study, liposomes were labeled with folate and an anti-EGFR antibody to further improve the specificity of tumor targeting. Although additional proof-of-concept experiments are needed for *in vivo* applications, a dual-ligand approach might be a future direction for enhancing the specificity of delivery.

One general expectation in ligand-modified nanomedicine is that the ligands actively improve the migration of nanoparticles from the bloodstream to target sites, such as tumor cells. This idea of "smart" ligands that guide nanoparticles from the rapidly flowing bloodstream to specific tumor sites is not fully realized in practice. Although several recent studies have shown dramatic increase in tumor accumulation of ligand-modified nanoparticles, others have consistently reported the lack of enhanced tumor tissue accumulation, even after high-density ligand modification. As discussed by the authors of these recent studies [80], most ligand-grafted nanoparticles arrive at tumor sites, not through the active guidance of ligands but through the predominant EPR effect.

Several approaches have been suggested for improving the penetration of nanoparticles through vascular endothelial barriers. One such approach is to increase the action of the EPR effect for both passive and targeted delivery of nanomedicines. Several groups have attempted to enhance EPR effects by administration of nitric oxide donor chemicals [102]. Additional approaches include the use of components for vascular targeting [98] and the design of multifunctional nanoparticles with bio-inspired penetration enhancers [103].

Although conjugated ligands do not appear to have a profound effect on the tumor accumulation of nanomedicines, they may contribute to enhancing tumor cell uptake of nanoparticles after extravasation, as suggested by the case of folate-modified micelles [80], described earlier. These and similar studies suggest that the greater anticancer efficacy of ligand-modified nanoparticles, despite similar accumulation at tumor sites, may be due to enhanced intracellular delivery.

After the arrival of ligand-modified nanomedicines at tumor tissues, the remaining challenge is penetration through the tumor mass. Owing to their size, nanoparticles at tumor sites have been shown to accumulate mainly in the peripheral area of the vasculature, rather than penetrating deeply into the tumor mass [78]. Reducing the sizes of nanoparticles in the tumor microenvironment has been suggested as a way of overcoming the size-dependent hindrance of nanoparticle penetration into the tumor matrix [104]. In this study, 100 nm nanoparticles were shrunk to a size of 10 nm by the action of proteases that are highly expressed in the tumor microenvironment. Such an approach might provide a framework for subsequent efforts to overcome the penetration limitation.

The composition of engineered nanoparticles is an important topic in the commercialization of nanomedicine. Currently, the most widely used method—chemical tethering of ligands onto preformed nanoparticles—has several limitations with respect to manufacturing and quality control [105]. The underlying chemistry

requires optimization to prevent batch-to-batch variability and variations according to the types of ligands and vehicles [106]. Complicated synthesis procedures also require complex purification procedures, which typically lead to expensive and time-consuming scaling-up efforts. With this manufacturing issue in mind, recent studies have demonstrated the advantages of self-assembly, prefunctionalization, and genetic engineering strategies in eliminating or minimizing complex manufacturing processes.

Ligand-engineered nanomedicines need to be used in conjunction with patient-tailored diagnostic tools to achieve the best therapeutic outcome. Depending on the cancer type, the expression levels of the receptors for targeting ligands may vary. Moreover, only patients that overexpress the specific receptors would be responsive to the ligand-modified nanomedicine. Thus, for optimal therapeutic efficacy, patients may need to be diagnosed in advance to determine whether they are likely to be responsive to a specific ligand-modified nanomedicine.

## 2.4 CONCLUSIONS

A variety of *in vivo* applications of ligand-engineered nanoparticles have been described. Despite the merits of engineered nanoparticles, remaining *in vivo* barriers can severely limit the activity of these particles after reaching tumor sites. At present, an ideal nanoparticle that satisfies all the requirements for successful clinical trials does not exist. However, the first and difficult steps toward developing a concrete understanding of the drawbacks have been taken, and related research has already been started to conquer them. As these obstacles are surmounted, the list of clinically successful nanomedicines is expected to grow in the near future.

## 3.1 INTRODUCTION

As with the development of recombinant DNA technology, gene therapy emerged as a promising technology that would drastically improve the practice of medicine for treating inherited and acquired diseases. The idea underlying gene therapy is to treat human disease by the transfer of genetic materials into specific cells of the patient [1]. Nucleic acids, the fundamental elements that precisely controlled the expression of proteins, are very appealing therapeutic candidates due to the simplicity of the drug development strategy and minimal side effects compared with conventional drugs. Moreover, the discovery of RNA interference (RNAi) by Fire and Mello in the late 1990s has opened up an entirely new field of "gene therapy," using small RNA fragments that potently knockdown the target gene expression with high specificity and efficiency [2]. Gene therapy has hardly made its mark in medicine. Successful implementation of gene transfer in the clinic requires drug delivery techniques that can efficiently and specifically deliver nucleic acids to the site of action after systemic administration.

The physicochemical properties of nucleic acid, such as vulnerability to nucleases, high anionic charge content, and high molecular weight (MW), preclude naked unformulated molecules from performing their functions after systemic delivery. Therefore, a delivery vector should facilitate nucleic acid therapeutics to access the

target cell, cross the cell membrane, escape the endosome compartments, and reach the sites of action, which is the cytoplasm for small interfering RNA (siRNA) and microRNA, and the nucleus for plasmid DNA (pDNA). Apart from physical methods such as electroporation [3] and hydrodynamic injection [4], there are two major classes of gene delivery vehicles that have been extensively investigated and developed to deliver nucleic acids to the target cells *in vivo*: viral and nonviral vectors. The former class harnesses the extremely high transduction efficiency of virus particles to infect target cells. For this purpose, the viral genome is genetically modified to deplete virulent and proliferation elements, leaving only the expression machinery in most cases. However, this class of vectors could stimulate serious immune responses [5] or result in unwanted host genome integration, which in rare cases would induce cancer development [6,7]. The latter vectors are composed of liposomes, polymers, inorganic materials, and nucleic acid conjugates. The synthetic vectors, compared with their counterparts, are easier for scale-up production, lower in immunogenicity, and cheaper in manufacture cost. Although favorable in many aspects, nonviral vectors suffer from relatively low delivery efficiency due to multiple barriers between the site of administration and the site of action. Ever since the first landmark publications in 1987 [8], cationic liposome based lipid nanoparticles (LNPs) turn out to be the most widely used and efficient nanometric device for *in vitro* delivery of nucleic acid. Cationic liposomes condense DNA into an ill-defined particulate structure (lipoplex) with excess positive charges, which allow efficient, but nonspecific, binding with the negatively charged cell surface and subsequent internalization [9]. The condensation of DNA also results in protection from enzymatic degradation. Effective as they appear *in vitro*, most of the LNPs failed or behaved far from satisfactory *in vivo*, especially for systemic delivery to solid tumor.

In this chapter, we first elucidate the extracellular and the intracellular barriers the LNPs encounter after systemic administration. Understanding the challenges in the delivery will lead to a rational design of novel lipid molecules or nanometric devices that could address these challenges. Next, we use a bottom-up strategy to identify the latest progression in lipid component development in the LNPs, and then compare various formulations that were exploited to encapsulate nucleic acid for successful *in vivo* delivery. The nucleic acids in this review include pDNA, siRNA, and antisense oligonucleotide (ODN), which either serve for gain of function or loss of function to treat various diseases.

## 3.2 BARRIERS TO SYSTEMIC GENE DELIVERY

Except for some directly accessible tumor sites after surgery ablation, tumor sites are typically only reachable through systemic administration of therapeutics in the bloodstream. Unfortunately, for the LNP-based nucleic acid delivery systems, multiple barriers exist extracellularly and intracellularly. These barriers substantially impede the successful delivery and therefore undermine the efficacy of delivered therapeutics.

### 3.2.1 Extracellular Barriers

Extracellular barriers refer to the hurdles imposed on the LNPs in the blood circulation before tumor cells take them up. These barriers include the liposome instability in serum, reticuloendothelial system (RES) uptake, vascular endothelium, and extracellular matrix (Figure 3.1).

Positively charged surface, found in most LNPs, results in strong protein adsorption when they are exposed to the blood serum where a high concentration of proteins with countercharges are present. The protein adsorption leads to agglomeration of the LNPs, followed by entrapment in the lung capillary and in the spleen macrophage enriched mesh tissue [10]. Some of the adsorbed blood proteins, for example, IgM and C4, are the known opsonins that facilitate the uptake of the LNPs by the RES cells, mainly the liver Kupffer cells and the splenic macrophages [10]. Conventional LNPs that encapsulate nucleic acid usually have a short blood circulation half-life, which could be substantially prolonged by coating the particles with polysaccharides or poly(ethylene glycol) (PEG) residues [10,11]. The hydrophilic coating endows the LNP with resistance to RES and hence the coated formulation is named *stealth liposomes*. Prolonged circulation provides more opportunity for LNPs to access the tumor site.

**FIGURE 3.1** Illustration of barriers to intravenous delivery of gene therapeutics. After LNP is intravenously injected into human body, serum protein tends to be adsorbed to the surface of LNP, destabilizing colloidal stability of LNP and causing the release of cargo (Inset I). The RES in the liver may take up LNPs, which reduces half-life of LNPs in the blood circulation (Inset II). Circulating LNPs extravasate into the interstitial space tumor tissue through the leaky endothelial lining and result in high accumulation in the tumor tissue due to the lack of lymphatic drainage (Inset III). However, LNPs have to traverse through the crowded extracellular matrix against the increasing fluid pressure to access the proximity of cancer cell.

Egress from the bloodstream and across the endothelial barriers also poses an insurmountable obstacle for liposome-mediated nucleic acid delivery. Molecules larger than 5–10 nm cannot readily traverse the capillary endothelium of healthy tissue [12] but keep circulating until they are cleared from the blood by renal clearance or other mechanisms. Most solid tumors, liver, and spleen allow the extravasation of large molecules or particles due to different anatomical characteristics of the endothelium in these organs [13]. It was reported by Maeda that tumor vascular has elevated permeability, which accounted for higher extravasation of macromolecules into interstitial tissue spaces [14] and a prolonged retention due to deficient lymphatic drainage [15]. This tumor-specific feature was named *enhanced permeability and retention* (EPR) effect, which has been extensively exploited as the major passive tumor-targeting strategy to achieve a higher accumulation in the tumor than plasma or other tissues. After extravasation from the blood vessel to the tumor site by the EPR effect, the LNPs are required to penetrate into the extracellular matrix filled with polysaccharide and protein network to gain access to the tumor cell membrane. This matrix permits only diffusion of small molecules and proteins yet not the conventional LNPs which are usually 100 nm or larger. Furthermore, the defective lymphatic elevates the interstitial pressure in tumor mass, which leads to radially outward convection opposing the inward diffusion [16].

### 3.2.2 Intracellular Barriers

Provided that the LNPs have circumvented all the potential extracellular barriers and traveled to the cellular surface after the "Odyssey Journey," with physical integrity and biological activity, there are still several major intracellular barriers that hinder foreign genetic materials from being delivered to the nucleus of the cells for expression. They are (i) the cytoplasmic membrane, (ii) the endosome compartment, (iii) the intracellular trafficking, and (iv) the nuclear membrane (Figure 3.2).

The LNPs may nonspecifically interact with cell surface followed by endocytosis. Studies have also demonstrated that internalization pathway and intracellular routing of particles is size dependent. The clathrin-mediated endocytic pathway has a size limit for internalization of ~200 nm in diameter. As the size increases, caveolae-mediated internalization becomes the dominant internalization pathway [17], and the LNPs are less likely to go through the endosome route. In order to realize targeted gene delivery, the LNPs are modified with various biologically active moieties such as arginine-glycine-aspartate (RGD) peptide, folate, anisamide, and transferrin, which can be specifically recognized by certain receptors that are overexpressed on the cancer cell surface and facilitate the internalization of the LNPs. The receptor-mediated internalization of LNPs is primarily via endocytotic pathway.

After cellular uptake via endocytosis, the LNPs are encapsulated in the membrane vesicles derived by invagination of clathrin-coated pits, namely, endosomes. The pH in the lumen of early endosomes gradually experiences a drop from neutral to pH 6.0 as the vacuolar ATPase proton pump is activated. As endosomes mature, the pH value continues to drop to 5.0 when late endosomes fuse with lysosomes [18]. Nucleic

**FIGURE 3.2** Schematic illustration of proposed pathway of gene delivery mediated by the LNPs. The targeting motif on the surface of the LNPs binds to the receptor overexpressed on the surface of cancer cells, allowing the internalization of the complexes via receptor-mediated endocytosis (Step I). The LNPs will be encapsulated in the endosomal compartment. The cargo needs to be released into the cytoplasm before the endosomes fuse with lysosomes (Step II). The cargos such as siRNA, mRNA, or miRNA will take effect in the cytoplasm as released. For pDNA, the carrier has to escort the cargo through the intracellular matrix until it reaches the periphery of the nucleus (Step III). If the size of the LNP complexes is more than 40 nm, the complex can enter the nucleus only at the mitosis phase of the cell cycle when the nuclear membrane dissolves. If the LNP complex is small enough (<40 nm), the complex may pass through the nuclear pore complex (NPC) (Step IV). Inside the nucleus, the pDNA will be decomplexed from the carrier for transcription.

acids that are entrapped in the endosome are subject to degradation if they have not escaped from the endosome before endosome–lysosome fusion occurs. This usually leads to poor efficacy because nucleic acids would not ultimately reach the cytoplasm or nucleus. Therefore, endosome entrapment is always considered one of the major intracellular barriers to nonviral gene delivery. In general, when the LNPs are endocytosed, the cationic lipids can interact with anionic membrane lipids and form ion pairs. Hence, the endosome membrane is destabilized by the formation of hexagonal phase ($H_{II}$), and nucleic acids are released into the cytoplasm subsequently [19].

Once successfully released into the cytoplasm, cargos such as siRNA, antisense RNA, miRNA, and mRNA could directly take effect without further transportation. However, pDNA must traverse through cytoplasm to reach the nucleus, which is a poorly characterized event so far and also considered a rate-limiting step in the

pDNA-mediated gene transfer. According to Goodsell's depiction [20], cytoplasm is a milieu that is crowded with high concentration of soluble proteins, subcellular organisms and compartments, cytoskeleton structure, and all other small molecules. All of these cellular components, especially three types of cytoskeletal filaments, namely, microtubules, microfilaments, and intermediate filaments, impose steric constraints on the diffusion of the macromolecules, slowing down long-range transport [21]. As a result, the passive diffusion coefficients of macromolecules are inversely related to their size. It seems very unlikely that Brownian motion is the major driving force for this colloidal nonviral gene delivery system whose particle size is between 80 and 150 nm [21]. In nature, adenovirus overcomes this obstacle by utilizing microtubule structure to travel to the perinuclear area after endosome escape [22]. This phenomenon has also been observed in nonviral gene delivery. Suh et al. employed multiple particle tracking (MPT) technique to determine that the velocity of polyethyleneimine (PEI)–DNA complexes transport was 0.2 μm/s, which is the same magnitude as movement of motor proteins dyneins and kinesins along the microtubule [23]. Although a few mechanistic studies have been done to get an in-depth understanding of the microtubule-mediated trafficking of these nanodevices to date, it is speculated that the motion of the LNPs could be greatly improved if they bear a signal molecule that can bind specifically to the microtubule [24,25].

The nuclear envelope is always considered a crucial barrier to efficient nonviral gene delivery. Over the past 10 years, mechanisms for the nuclear transport of pDNA have been investigated and described. Many approaches have been developed based on exploitation of these mechanisms. In general, when carrier–DNA complexes reach perinuclear membrane, there are three scenarios for the LNPs to finally reach nucleoplasm, which are categorized according to the particle size. When the particle size is below 10 nm, it can passively diffuse through the nuclear pore complex (NPC). However, this does not apply to most of the LNPs. When the particle size is above 40 nm, it tends to accumulate around the nuclear membrane and wait for the mitosis phase to enter the nuclear compartment when the nuclear envelope is dissolved. This is partly why growth-arrested cells and other non-dividing cells are considered difficult to transfect. Also, this accounts for the observed cell-cycle dependent expression pattern of the cells transfected by nonviral vectors. When the particle size is between 10 and 40 nm and the particle carries a nuclear localization signal (NLS), it could be actively transported into the nucleus through the nuclear pore complex (NPC) via the NLS-mediated nuclear importing machinery. NLS is a short basic amino acid sequence that can be recognized by importin-α, an NLS receptor, which then dimerizes with importin-β. The importin-αβ heterodimer complex then carries the NLS bearing cargo through NPC for nuclear transport. NLS has been incorporated into cationic lipids [26,27] and proved to facilitate pDNA nuclear entry. The location of NLS in the vector is of significant importance regarding the active functionality. The signal should be readily accessible to the importin protein. If NLS overlaps with the DNA-binding domain, there is a good chance that the NLS-directed nuclear transport would be compromised.

## 3.3 COMPONENTS OF LNPs

The components in the LNPs usually include various lipids, polymer (polypeptide or synthetic polymer) and lipid-PEG conjugates, and so on. There are extensive investigations on a rational design basis, to ameliorate the components of the LNPs for improved delivery efficiency. Here we review the most representative ones.

### 3.3.1 Cationic Lipid

The encapsulation of nucleic acids of various molecular weights, ranging from 20 base pairs to several thousand base pairs, essentially depends on the cationic charges of carrier molecules. A multivalent cation is the key component because the electrostatic interaction between the cationic lipid and the anionic cargos results in condensation of nucleic acid into nanometric particles through an entropy-driven process [28].

Commonly used cationic lipids are usually classified into three categories [29] based on the charges on their headgroups: (1) monovalent aliphatic lipids such as *N*-(1-(2,3-dioleyloxy) propyl)-*N*,*N*,*N*-trimethylammonium chloride (DOTMA) [8], 1,2-dioleyl-3-trimethylammonium propane (DOTAP) [30]; (2) multivalent aliphatic lipids with headgroups containing several amine functions such as dioctadecylamidoglycylspermine (DOGS) [31], 2,3-dioleyloxy-*N*-(2-[sperminecarboxyamido] ethyl-*N*,*N*-dimethyl-1-propaniminium bromide (DOSPA) [32]; (3) cationic lipid derivatives such as 3β-(*N*-(*N*′,*N*′-dimethylaminoethane)-carbamoyl)cholesterol (DC-Chol) [33] and bis(guanidinium)-tren-cholesterol (BGTC) [34].

The cationic lipids not only are responsible for DNA condensation but also play a critical role in interacting with the negatively charged cellular membrane and triggering an efficient endocytosis for uptake. This advantage is well exploited in nonspecific tissue culture transfection *in vitro*. Nevertheless, the advantage *in vitro* turns out to be the disadvantage *in vivo*. The positive charge is detrimental to *in vivo* transfection because the charges on the particle surface tend to attract negatively charged serum proteins, subsequently leading to fast blood clearance and poor tissue distribution for the aforementioned reasons.

This problem is addressed by either coating liposomes with neutrally charged PEG polymer, which not only screen the positive charge but also provide a hydrophilic steric barrier that significantly reduces protein adsorption. Alternatively, cationic lipids with a pH-sensitive ionizable headgroup emerge. With $pK_a$ slightly lower than 7.0, ionizable cationic lipid can efficiently condense nucleic acids at acidic pH and maintain a neutral or low cationic surface charge at physiological pH (7.4) after *in vivo* administration. This strategy provides sophisticated control over surface charge of the LNPs in the blood circulation and prevents nonspecific cellular uptake, representing a recent trend in the development of lipid materials for nucleic acid delivery, especially for siRNA.

The idea of incorporating ionizable lipids in nucleic acid delivery was first reported by Semple et al. [35]. In order to overcome the unfavorable pharmacokinetics (PK) and toxicity profiles for cationic lipid based LNPs, a novel ionizable

aminolipid (1,2-dioleoyl-3-dimethylammonium propane, DODAP) was used to efficiently encapsulate antisense ODN in the LNPs. Later, another ionizable lipid DLinDMA (1,2-dilinoleyloxy-*N*,*N*-dimethyl-3-aminopropane) has proven to be highly effective regarding *in vivo* transfection efficiency [35]. The liposome made of DLinDMA showed close to neutral surface charge in the blood circulation at physiological pH. After endocytosis, the pH drops in the endosomal compartment, and the lipid is protonated. The cationic lipid is supposed to interact with naturally occurring anionic phospholipids in the endosomal membrane by electrostatic interaction, forming ion pairs that induce conformational transition from bilayer to hexagonal $H_{II}$ phase, which destabilizes endosomal membrane for nucleic acid release. The LNPs formed with ionizable lipids have been tested in rodents, nonhuman primates [36], and is now being evaluated in human clinical trials.

As a benchmark for the design of novel ionizable cationic lipid, a pool of ~1200 lipid molecules with various modifications on the hydrocarbon chain, linker, and headgroup have been implicated [37]. A sensitive mouse Factor VII model was used as the *in vivo* screening system to evaluate liposome-based hepatocyte siRNA delivery efficiency [38]. A series of modifications have been implemented in the headgroups, linkers, and hydrocarbon chains [37]. The strategy for the headgroup modifications was to change the size, acid-dissociation constant, and number of ionizable groups and to evaluate the corresponding delivery efficiency. Piperrazino, morpholino, trimethylamino, or bis-dimethylamino cations were tested, with none showing better performance than dimethylamino headgroup of 2,2-dilinoleyl-4-dimethylaminomethyl-[1,3]-dioxolane (DLin-K-DMA). In addition, the distance between the dimethylamino group and the dioxlane linker was varied by introducing various numbers of the methylene group. The results showed that insertion of a single additional methylene group (2,2-dilinoleyl-4-(2-dimethylaminoethyl)-[1,3]-dioxolane) produced a dramatic increase in potency with an *in vivo* ED50 as low as 0.1 mg/kg, which turned out to be the lowest dose for silencing Factor VII *in vivo* [37].

Linker region was optimized by testing different rates of chemical or enzymatic stability and hydrophobicity according to modifications. The results indicated that rapidly degradable linker did not necessarily correlate with high *in vivo* activity. Highly reactive ester-containing lipid showed reduced *in vivo* activity compared to less reactive alkoxy-containing lipid. The lipids were speculated to undergo an unwanted degradation before the vector successfully delivered a cargo to the cells.

For hydrocarbon chains, a correlation between number of *cis* double bonds in the chains and delivery activity was studied. It was determined that linoleyl lipid containing two double bonds per hydrocarbon chain is optimal in a transfection model, mediated by fusion with endosomal membrane for cytoplasmic release of the nucleic acid [39].

### 3.3.2 Neutral Lipid

In order to avoid unfavorable PK caused by positive surface charge after systemic delivery, Sood and colleagues have developed a method to formulate siRNA in a

neutral lipid dioleoylphosphatidylcholine (DOPC)-based-liposome for systemic delivery [40]. Since DOPC has an amphiphilic choline headgroup, which displays neutral charge at physiological pH, a conventional approach to encapsulate siRNA with a charge–charge interaction is not applicable here. Therefore, a *tert*-butanol/Tween 20 system was employed to encapsulate siRNA through a series of process including evaporation, lyophilization, and rehydration [40]. The loading efficiency of siRNA was estimated to be about 65%. The DOPC liposome was able to deliver anticancer siRNA in metastatic liver carcinoma [41,42] and orthotopic ovarian cancer model [40,43–45] with high efficacy. Although the results are impressive, the mechanism of siRNA encapsulation in neutral LNPs was not elucidated, and physicochemical properties of the LNPs were poorly characterized.

With the same aim in mind (to reduce cationic charge on the surface of liposome), Herscovici and colleagues designed a series of lipid molecules with thiourea headgroup on the basis of the observation that bis-thiourea moieties selectively bind to dihydrogen phosphate via multitopic hydrogen bonding [46]. Nevertheless, the transfection was unimpressive due to the hydrophobic nature of the lipopolythiourea liposome, which hinders the interaction with the cell membrane [46]. This feature, however, could be exploited to avoid nonspecific cell uptake and be overcome by postgrafting with targeting ligands to facilitate internalization [46]. The absence of cationic charges endowed the liposome with an improved PK profile *in vivo*, yet the benefit did not increase the tumor accumulation according to the proposed EPR effect [47]. It is also worth noticing that thiourea LNPs achieved a similar transfection level as cationic LNPs, although internalization of the thiourea LNPs was determined to be sixfold less than that of the cationic LNPs. This high expression level despite low uptake efficiency indeed revealed a favorable release profile for lipothiourea after internalization, which was measured to be three times faster than the cationic liposome. This fast unpackaging characteristic is attributable to the relatively low hydrogen bond-based interaction between phosphate group of nucleic acid and thiourea lipid [48] when compared with electrostatic interaction.

### 3.3.3 Anionic Lipid

Although anionic lipids alone cannot condense nucleic acid through electrostatic interaction, they are usually formulated into nanometric particle to reduce the nonspecific cellular uptake and adsorption by positively charged serum protein for *in vivo* nucleic acid delivery [49–52]. In this approach, nucleic acids are usually condensed with excessive polycations such as PEI or protamine to form a core complex with positive surface charge. Preformed anionic liposomes are subsequently added to the system, coating the core complexes with bilayer lipid membrane. Chen et al. formulated liposome/polycation/DNA (LPD)-II by coating liposome, composed of 1,2-dioleoyl-*sn*-glycero-3-phosphate (DOPA), 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE), and cholesterol, on protamine-condensed siRNA. The LPD-II formulation showed much lower immunogenicity compared with the cationic liposome coated LPD nanoparticles, which widened the therapeutic window for the therapeutic applications [52].

Another approach, reported by Srinivasan and Burgess, utilized anionic liposome as a gene carrier [53]. In their study, divalent cations (such as $Ca^{2+}$, $Mg^{2+}$, $Mn^{2+}$, and $Ba^{2+}$) were incorporated into the system to achieve the complexation between the nucleic acid and the anionic lipids. High percent of transfection was achieved *in vitro* in the presence and absence of serum and demonstrated minimal cytotoxicity. Although the hydrodynamic size of the complexed particles was at the submicron level, which was not suitable for *in vivo* applications, this formulation provided a novel way of using anionic liposome for transfection.

### 3.3.4 PEG–Lipid Conjugates

As proposed by Allen, "If you want to be invisible, look like water" [54]. For longer blood circulation, which is a prerequisite for efficient gene delivery after systemic administration, it is necessary to coat the surface of the LNPs with neutral and hydrophilic polymers such as PEG. Klibanov et al. have reported, for the first time, a prolonged liposome circulation after PEGylation back in 1990 [11], a landmark publication for long circulation liposomes. Later, Campbell observed an increased tumor accumulation of PEGylated cationic LNP due to EPR effect [55]. To date, PEG is the most appreciated hydrophilic polymer with a tunable size (normally from 300 to 25,000 Da), particularly high biocompatibility and versatility. Surface modification with PEG stabilizes liposome in the presence of serum and extends the blood circulation after administration, as a result of reduced level of protein adsorption to the hydrophobic area of the LNPs. This effect predominantly depends on the molecular weight, density, conformation, and flexibility of the PEG chain. Vonarbourg and Benoit did an excellent review on this subject [10]. It was demonstrated that the protein adsorption efficiency decreased with an increase of MW of PEG chain [56]. Most authors advocate an efficient MW in the range 1500–3500 Da [10]. In addition, the PEG density and conformation, which not only depend on the MW of PEG chain, but also the size of LNPs, are of great importance to resist opsonin penetration. Briefly, smaller LNPs with larger curvature, or smaller radius, need a higher density of PEG compared with larger ones. The conformation of PEG chain on the surface is dictated by the relationship between the distance ($D$) of the anchorage sites and the gyration radius ($R_F$). When $D > 2R_F$, the grafted PEG chain is in a mushroom-like conformation. However, when there is more PEG grafted on the surface of the lipid bilayer, which makes polymer chains closer (in such case, $D \ll R_F$), polymer chains tend to appear as a brush-like conformation. Brush conformation was believed to be most effective in repelling against the complement components, more resistant to phagocytosis (Figure 3.3).

Various lipid-PEG conjugates are inserted into the lipid bilayer membrane during or after the formation of the LNPs. The hydrophobic interaction between the anchor lipid of the conjugate and hydrophobic chain of the membrane lipid is the major force that keeps the PEG on the surface of the LNPs. Since the lipid-PEG conjugate is soluble in the aqueous bulk, the molecule also tends to shed from the liposome surface especially under a sink condition. Cullis et al. have taken the initiative to

**FIGURE 3.3** Putative PEG conformation with respect to PEG concentration in the surface of LNPs. Conformations of the polymer chains are dictated by the relationship between the distance ($D$) between the anchorage sites of two chains and the gyration radius ($R_f$). When $D > 2R_f$, PEG chains form a mushroom-like structure. Protein tends to be adsorbed to the surface of the LNPs. When $D \ll R_f$, PEG chains assume brush-like conformation. The high-density, brush-like PEG configurations would sterically suppress the deposition of large proteins.

investigate and have tried to figure out the correlation between different lipid-PEG conjugates and transfection efficiency of the LNPs prepared by the dialysis method [57–60]. It was demonstrated that longer acyl chain in the lipid-PEG conjugates stabilized the particle, whereas the transfection efficiency was compromised due to less interaction between the cationic lipid and cell membrane. On the other hand, shorter acyl chain length resulted in a readily dissociable surface coating that could transform the LNPs from a stable form into a transfection-competent form. It was also demonstrated that the composition of acyl chain determined the rate and extent of PEG extraction, which was reflected on the elimination rate in the bloodstream. Adlakha-Hutcheon et al. reported the relationship between the anchor chain length and liposome circulation time [59]. In their study, a PEGylated programmable fusogenic vesicles (PFV) stabilized with PEG was employed to exhibit time-dependent destabilization in body. Three types of PEG-lipid with different acyl chain length were used to coat the surface of liposomes: 1,2-dimyristoyl-*sn*-glycero-3-phosphoethanolamine (DMPE, C14), 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine (DPPE, C16), and 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine (DSPE, C18). The results revealed that formulation with the shortest acyl chain (C14) were rapidly eliminated from the circulation. On the other hand, formulations with DPPE–PEG (C16) and DSPE–PEG (C18) showed a prolonged half-life for 4 and 24 h, respectively [59]. A complete protection is favorable for long-circulating liposome in the blood stream.

Shedding of the PEG coating is preferred once the LNPs are in the proximity of targeted cells, because the hydrophilic PEG coating tends to prevent the interaction between cell membrane and liposome, impeding the internalization of the LNPs. Grafting of a ligand on the distal end of PEG chain can circumvent this dilemma, facilitating internalization through receptor-mediated endocytosis. However, caution needs to be taken, as the distal end ligand can lead to protein adsorption, which speeds up the blood clearance especially when the ligand density is high [61]. After the LNPs are internalized into the cells through an endocytotic pathway, either the cationic lipid needs to interact with negatively charged endosome membrane or some fusogenic lipid, such as DOPE, needs to interact with and destabilize the endosome membrane structure. Under such circumstances, the presence of PEG chain might sterically hinder the interaction between the carrier lipids and endosomal membrane lipid, substantially reducing cytosolic release efficiency. Therefore, it is desirable that PEG coating is shed away to allow the interaction between fusogenic lipid and endosome membrane. Although the continuous shedding effect of PEG takes place after systemic delivery due to the sink condition in the blood, it is difficult to have a complete control over the shedding rate to make sure that shedding is complete when LNPs are entrapped in the endosome of the targeted cells. This kind of "passive" shedding demands extensive characterization of lipid-PEG conjugates and their interaction with the *in vivo* environment. Therefore, a series of stimulus-responsive-lipid-PEG have been developed to realize a controlled shedding of PEG. The idea is to introduce a linker between the lipid and PEG chain, which is cleavable under certain stimulus exclusively in endosome such as low pH [62–65], reducing agents [66], or enzymes [67,68]. Some linkers are designed to respond to extracellular environment of the tumor cells, such as low pH and the presence of matrix metalloproteinases [69]. Such rational designs of shedding process significantly promote the drug release and target cell interaction process.

## 3.4 FORMULATIONS OF THE LNP FOR NUCLEIC ACIDS ENCAPSULATION

The most conventional way of encapsulating nucleic acids with cationic liposome is to mix the two components to form a lipoplex, which however does not have much control over the structure and homogeneity of the complex. Various approaches have been investigated and developed to form the LNPs with desired structure so as to have more control over the performance of nanoparticles *in vivo*.

### 3.4.1 Self-Assembly

One of the most exploited strategies of self-assembly is to use a polycation to condense nucleic acid into anionic compact core complex, upon which cationic liposomes are coated on the surface to form a membrane-core structure. In the mid-1990s, the Huang laboratory used poly(L-lysine) and protamine [70] to precondense pDNA before incorporating the pDNA into the preformed cationic liposome

**FIGURE 3.4** Schematic illustration of LPD preparation. Briefly, anionic mix of siRNA and calf thymus DNA is condensed by protamine. The negatively charged condensates are then coated by cationic DOTAP–cholesterol liposome to form the core-membrane structure complex. The nanoparticle is PEGylated by incubation with DSPE–$PEG_{2000}$–anisamide (AA) and DSPE–$PEG_{2000}$ micelles.

containing 3β-[*N*-(*N*′,*N*′-dimethylaminoethane)-carbamoyl] cholesterol (DC-Chol) and DOPE. The membrane-core-structured LNPs were named as lipid-polycation-DNA (LPD) nanoparticles. The precondensation dramatically decreased the particle size of the pDNA–liposome complex and effectively protected DNA from nuclease degradation [71]. This formulation not only enhanced the transfection efficiency of the LNPs by up to 28-fold *in vitro* [71] but also demonstrated *in vivo* transfection capacity with minor modifications [70]. Later, Li et al. modified the formulation by coating the surface with DSPE–PEG and a sigma receptor targeting ligand DSPE–PEG–anisamide (Figure 3.4), which substantially increased *in vivo* siRNA delivery efficiency by fourfold and the gene silencing effect by two- to threefold [72]. Successful delivery of LPD to subcutaneous and lung metastatic tumors was believed to be due to reduced RES uptake by PEG coating, which resulted in higher tumor accumulation because of the EPR effect [73,74]. It is worth noticing that the negatively charged protamine/calf thymus DNA/siRNA core played a critical role in supporting the lipid bilayer, allowing more surfactant-like DSPE–PEG conjugates to be inserted in the membrane without ripping off the lipid membrane [75]. This high density of sheddable PEG significantly improved the PK of LPD nanoparticles in the blood stream [76].

With a similar approach, Harashima et al. have devised a series of lipid based core-shell structured nanocarriers, namely, multifunctional envelope-type nano-device (MEND) [68,77–93]. In these formulations, stearyl-octaarginine and cholesteryl-GALA(WEAALAEALAEALAEHLAEALAEALEALAA) were incorporated into the preformed lipid membrane mixed with DOPE and cholesteryl hemisuccinate (CHEMS) [81,83,84,90,91]. Slightly different from the LPD formulations, the pDNA/protamine or PEI condensates in water are added to the blown lipid film. The hydration of lipid membrane initiates the formation of liposome, which coats the condensates subsequently. The final nanoparticle is sonicated to ensure homogeneity. MEND has been employed to deliver genes to

the liver [83] or the lung [82] with the surface modification of octaarginine or IRQ peptide (IRQRRRR). The octaarginine or IRQ peptide enabled the internalization of MEND nanoparticles through macropinocytosis and caveolar endocytosis, respectively. The GALA peptide on the surface was also used as a pH-responsive fusogenic peptide that destabilizes membrane structure at acidic pH in the endosome for cytoplasmic release of the cargo.

### 3.4.2 Detergent Dialysis

As an alternative to self-assembly, which usually involves preformed liposomes, a detergent dialysis method is used for lipid-based nanocarriers to encapsulate negatively charged nucleic acid [94]. The idea is to use nonionic detergent with a high critical micelle concentration to solubilize amphiphilic lipid molecule in aqueous solution in the presence of the nucleic acid so that nucleic acids were bound to free lipid instead of liposome. As the detergent is removed gradually by dialysis, cationic lipid and the associated nucleic acid are rearranged and form a vesicle structure that entraps the nucleic acid inside the liposomes. The name, stabilized plasmid-lipid particle (SPLP), is well recognized and represents a class of formulated LNPs prepared by the detergent dialysis method. This method forms 100 nm liposomes with higher trapping efficiency (60–70%) than those achieved by conventional methods such as reverse evaporation phase, extrusion, or dehydration-rehydration, which also usually result in large particle size due to aggregation [59,95].

With a similar idea, Jeffs et al. have developed a new procedure-spontaneous vesicle formation (SVF) to encapsulate pDNA [96]. A lipid solution containing cholesterol, distearoylphosphatidylcholine (DSPC), 1,2-dioleyloxy-*N*,*N*-dimethylaminopropane (DODMA), and 3-*O*-(2′(-methoxypolyethyleneglycol)$_{2000}$)-1,2-distearoyl-*sn*-glycerol (PEG–S-DSG) in 90% ethanol was used to mix with pDNA in the buffer. The mixing procedure resulted in the drop of ethanol concentration, which was insufficient to support lipid solubility. A lipid vesicle was subsequently formed to encapsulate pDNA. The pDNA-containing liposome was further diluted with buffer to further stabilize the metastable vesicles, resulting in a significant increase in DNA encapsulation from 60% to 90% [96]. The employment of a T-shaped mixing chamber ensured the reproducibility of SPLP, which showed the potential for scale-up manufacture for clinical studies.

Morrissey et al. adapted the detergent dialysis method to encapsulate chemically stabilized siRNA with a superb efficiency of 93% [97]. The specialized liposome, namely, stable nucleic-acid-lipid particle (SNALP), was composed of DSPC, cholesterol, PEG–C-DMA, and ionizable lipid DLinDMA. The LNP is formed with similar nucleic acid to lipid ratio and mean particle size (140 nm) regardless of the nucleic acid payload. The *in vivo* knockdown efficiency was evaluated in a mouse model of hepatitis B virus replication. The formulation drastically reduced the effective dose of siRNA delivery to 3 mg/kg/day and demonstrated a persistent knockdown effect up to 6 weeks with a weekly injection. Later, Zimmermann et al. has examined the siRNA delivery efficiency of SNALP by knocking down disease target apolipoprotein B (ApoB) in the liver of nonhuman primates. It was

demonstrated that a single injection of 2.5 mg/kg resulted in a sustained 80% silencing of ApoB mRNA expression in the liver till 11 days after injection [36]. The degree and duration of the gene-silencing effect was way beyond the data acquired from rodent animal studies. The outstanding effects may be attributed to species differences with respect to turnover time of RNAi. The report supported the clinical potential to realize RNAi therapies with the aid of SNALP delivery system.

### 3.4.3 Nanometric Calcium Phosphate/siRNA Precipitation

Co-precipitates formed between calcium phosphate and DNA have been used as an efficient method to transfect cultured mammalian cells to express exogenous genes since it was first reported by Graham et al. [98]. However, the application of this technique has been limited to *in vitro* transfection as a result of uncontrollable size and batch-to-batch variability of transfection efficiency [99]. Li and Huang have harnessed the low toxicity and pH-induced degradability of the co-precipitates and formulated a nano-sized calcium phosphate particles coated with liposomes for siRNA systemic delivery, namely, lipid–calcium–phosphate (LCP) [100,101]. The calcium phosphate particle is precipitated in an aqueous phase of a water/oil (cyclohexane) reverse microemulsion system stabilized with surfactants (IGPAL-520 and DOPA) (Figure 3.5). Size of the formed calcium phosphate amorphous precipitate is well controlled, as the surfactants on the surface prevent aggregation of the precipitates. siRNA is entrapped within the nanoprecipitate by the interaction between phosphate groups of siRNA and calcium ions. The lipid monolayer of DOPA is stabilized on the surface of the nanoprecipitate as a result of interactions

**FIGURE 3.5** Preparation of liposome–calcium–phosphate (LCP) nanoparticles.

between the phosphate groups of DOPA and calcium ions. IGEPA-520 is subsequently removed by repeated centrifugation and washing with ethanol. The final LCP is formed by incubating DOPA-stabilized calcium phosphate nanoprecipitates with outer leaflet lipids in an aqueous solution [100,101].

The LCP demonstrates a pH-responsive siRNA release profile. As the pH in the endosome starts to drop, calcium phosphate precipitates dissolve and release cargo. Meanwhile, the released calcium ions increase the osmotic pressure of endosomal compartments, destabilize the endosomal membrane, and facilitate the release of siRNA into the cytosol. This property substantially enhances delivery efficiency of the LCP. The *in vitro* half maximal inhibitory concentration $IC_{50}$ was determined to be 60 nM, which was three to four times lower than that of LPD (200 nM) [100,101]. The LCP nanoparticle has been demonstrated to knockdown the luciferase activity in a B16F10 lung metastasis model with an $ED_{50}$ of 0.06 mg/ml. The co-delivery of VEGF, MDM2, and c-myc siRNA formulated in LCP nanoparticle significantly suppressed the lung metastasis (~70%) with a relatively low dose (0.36 mg/kg).

## 3.5 ORGAN-SPECIFIC DELIVERY OF NUCLEIC ACIDS WITH LNPs

The advancement of nanoparticles has triggered the site-specific delivery of nucleic acid based therapeutics. Moreover, owing to the different anatomical structures and physiological functions of major organs, particularly the endothelium status and the RES, various strategies harnessing the organ-specific features have been developed so as to specifically deliver nucleic acid loaded LNPs into targeted organs.

### 3.5.1 Brain-Targeted Delivery

The brain is highly protected from the periphery by two major barriers, the blood–brain barrier (BBB) and blood–cerebrospinal fluid barrier (BCSFB). The former barrier is primarily responsible for the maintenance of homeostasis of the central nervous system (CNS). The BBB is composed of nonfenestrated microvessel endothelial cells with continuous tight junctions that limit the transport of macrophages, xenobiotics, and some other endogenous metabolites [102]. In addition to the physical barrier reflected by the tight junction, there is a metabolism-driven barrier that is manifested by the expression of several receptors, ion channels, and influx/efflux transport proteins [103]. Therefore, the BBB has been the major barrier that compromises the efficacy of most therapeutics including macromolecular drugs.

Of many brain diseases, primary malignant brain tumors are the most lethal ones. As the primary tumors or metastases begin to grow beyond 1–2 mm in diameter within the brain parenchyma, the BBB is compromised both structurally and functionally with features of highly tortuous, disorganized, and permeable vessels [104]. These features are not different from tumors arising elsewhere and could be exploited for the delivery of therapeutics based on the EPR effect. Nevertheless, for other brain diseases such as neurodegenerative disorders or

ischemic stroke, the BBB still remains intact and is able to block the pharmacological reagents from crossing the endothelium to access the target site. The advancement of nanotechnology has tackled the problem with great success for CNS drug delivery since the nanocarriers could selectively interact with endothelial microvessels after modification with targeting moieties and result in a high local concentration of therapeutics in the brain parenchyma [103]. The LNPs are probably the most investigated and clinically tested due to the long circulation time and low toxicity [105]. The major strategies for the development of LNPs to cross the BBB is through transcytosis, initially observed as a mechanism by which iron-loaded transferrin is transported to the parenchyma of the brain [106]. Transferrin or antibodies against transferrin receptor have been extensively used for the surface modification of these LNPs for brain delivery [107–113].

The most outstanding LNP that has been well studied and applied to various brain disease models is the Trojan horse liposome (THL), developed by Pardridge et al. [108]. The surface modifications with targeting ligands for insulin receptor or transferrin receptor expressed on the surface of BBB enable selective transport of the LNP from the luminal side of the endothelium to the brain parenchyma. Additional grafting of neuron-specific ligands facilitates the nanoparticle uptake via receptor-mediated endocytosis. The delivery efficiency of the LNPs has been demonstrated in gene therapy for the treatment of Parkinson's disease model in rats [109,114,115], VII mucopolysaccharidosis model in mice [111], and RNAi therapy targeting epidermal growth factor receptor with shRNA in mouse glioblastoma [116].

An alternative strategy to enhance brain delivery is to coat the nanoparticle with cell-penetrating peptides such as TAT and octaarginine (R8) since these peptides increase the selectivity of BBB and promote drug trafficking [117]. Although the mechanism of action was not well elucidated, it was observed that the surface charge of the particle played an important role in the brain delivery [117,118]. This implies that electrostatic interaction between the positively charged particle and the lectins on the microvessel endothelial cells might trigger the endocytosis.

### 3.5.2 Liver-Targeted Delivery

Among various organs, the liver has drawn most attention due to its critical role in the metabolism. Moreover, the liver has a unique sinusoidal endothelium, which processes open pores or fenestrae lacking a diaphragm and a basal lamina underneath the endothelial lining with the pore size around 100 nm in diameter [119]. This property of the well-perfused organ makes it easy for the LNPs to extravasate to reach the interstitial space of the liver tissue. However, Kupffer cells, the macrophages of the liver, lay in ambush in the endothelium to capture and destroy foreign particles. Any successful nanoparticle drug delivery vectors will have to evade the Kupffer cells before accessing other cells of the liver. In this regard, a dense PEG coating usually disguises the LNPs from being recognized by the RES. The presence of a hepatocyte-specific targeting ligand diverts the LNPs from highly phagocytic cells and enhances the uptake by hepatocytes. Since hepatocytes uniquely express

asialoglycoprotein receptor on the cell surface, galactose is widely exploited as a ligand for liver-specific gene transfer [120–122].

Another strategy to direct LNPs to hepatocytes is to take advantage of apolipoprotein (Apo), a component of high-density lipoprotein (HDL) that guides the transport of lipids to the liver for processing as a natural ligand for the scavenger receptor on hepatocytes. The hydrophobic domain in the Apo prompts the interaction between the Apo and the LNPs, essentially forming an artificial HDL. The incorporation of the Apo as a targeting ligand makes the LNPs predominantly taken up by the liver cells with well-characterized mechanism [123,124]. LNPs have proven to be highly efficient carriers for the liver delivery. This is probably because the circulating LNPs could interact with serum proteins and acquire protein components that guide the transport of the LNPs to specific cells [125,126]. Apolipoprotein E (ApoE), shown to be capable of enhancing the uptake into hepatocytes through low-density lipoprotein receptor (LDLR), was exploited as an "endogenous ligand" and an alternative to an exogenous targeting ligand [127]. The functionality of the proposed endogenous ligand was examined by Akinc et al. in LDLR−/− mice and ApoE−/− mice, respectively. It was demonstrated that the hepatocyte-specific delivery of the neutral liposome is ApoE mediated and LDLR dependent [127].

In addition to the aforementioned rational-based design of LNPs for the liver delivery, some molecules, which have demonstrated liver-specific properties, are also explored for the modification of LNPs for liver specificity. It was observed that R8-peptide-modified LNPs largely accumulated in the liver after intravenous administration and transfected hepatocytes with high efficiency. The uptake was proven to be R8 density dependent [128,129]. The liver-specific biodistribution is likely attributable to a unique property of R8 given that this type of peptide represents a promising device for specific liver delivery [130].

### 3.5.3 Lung-Targeted Delivery

Owing to the anatomical structure of the lung, rich in microcapillaries, gene transfer to the lung could be performed through systemic administration similar to other organs. Genetic therapeutics could also be administered noninvasively via airways. Because of the limited scope of this review, we focus the discussion mainly on the former route. The LNPs with cationic surface charge will preferably accumulate in the lung tissue without any modification since there is an excellent chance for them to interact with microcapillary endothelium and trigger the endocytosis [131]. Although the non-PEGylated LNPs are more likely to be opsonized and taken up by the macrophages in the liver and the spleen, it still results in a high level of transgene expression in the lung [131]. Recent studies have revealed that various tissue disorders are related to endothelium, particularly tumor angiogenesis. Therefore, the endothelium could serve as a therapeutic target for primary or metastatic lung tumors. Surface modifications with PEG and a tumor-specific targeting ligand can enhance the accumulation of liposome in the interstitial space of solid tumor and significantly increase the uptake of liposome by cancer cells [74,132,133].

### 3.5.4 Kidney-Targeted Delivery

Although the prevention and treatment of renal diseases is highly demanding, nonviral gene therapists have not paid as much attention to the kidney as to the liver and the brain. For one of the reasons, the kidney is not an organ that has the large accumulation of nanoparticles after systemic administration. Moreover, the signal from the kidney in the biodistribution study was often proven to be the fragments of dissociated nanoparticle, which was disposed through the glomerular filtration. Lai et al. tried to use Lipofectin formulation (DOTMA–DOPE) to deliver β-galactosidase gene to the kidney via intra-renal-arterial injection. The expression of the reporter gene was detected in the cortex and the outer medulla area and exclusively observed in the tubular epithelial cells [134]. Ito et al. used the same formulation to introduce inducible nitric oxide synthase (iNOS) gene into the kidney via intraureteral injection. The iNOS expression was detected in the collecting ducts, distal tubules, and glomerulus in the injected kidney and improved the renal function in unilateral ureteral obstruction [135]. Nevertheless, most of the kidney gene therapy has been conducted by viral vectors for high specificity and transgene expression.

## 3.6 CURRENT CHALLENGES TO THE DEVELOPMENT OF LNPs

The term *targeted gene delivery* indicated a predominant accumulation of genetic therapeutics in the intended tissues or even in the specific cell populations. This idea was originally conceived by Paul Ehrlich as the "magic bullet" that goes straight to the target cells to deliver cargos after systemic administration. The LNPs at the current stage, regardless of materials and formulations, are far from the ideal "magic bullet" because the biodistribution of most nanoparticles relies on both the properties of the nanoparticles and the vascular endothelium status of the organs or tumors. Although PEGylation could significantly improve the PK profiles of nanoparticles, drastically reducing the liver and spleen accumulations by the RES uptake and increasing the blood circulation time, the tumor accumulation of LNPs is reported to be around 5–10% of the injected dose. It has been noticed that the accumulation would not increase even if there were excessive LNPs circulating in the bloodstream. This suggested that a saturation state existed for the EPR-mediated tumor accumulation. Maeda et al. have investigated factors that affect tumor vasculature permeability and described a bradykinin-mediated pathway to account for the EPR effect [136]. Some intermediate molecules in the pathway such as bradykinin or NOS were targeted for the modulation of vascular permeability to enhance the EPR effect [136]. Nevertheless, there was only marginal increase in the tumor accumulation. Strictly speaking, there is no passive "targeting" if more than 90% of the administered dose goes elsewhere other than the targeted site. Furthermore, the degree of the leakiness of tumor vasculature is highly variable and heterogeneous even for the same type of xenograft implanted at the same site [137]. So far, the EPR effect has been the major driving force for nanoparticle delivery to

solid tumors. It is imperative that some alternative mechanisms be exploited in order to enhance tumor accumulation of nanoparticles to meet the therapeutic challenge.

## 3.7 FUTURE PERSPECTIVES

The lack of satisfactory gene delivery systems impedes the application of the therapy in the medical practice. Liposome-mediated gene delivery appears to be most feasible and reliable compared with other nonviral vectors. This is by and large due to their relatively high rate of gene transfer efficiency, biodegradability, and cost-effectiveness. The emergence of ionizable catonic lipids, such as conditional catonic lipids, has revealed its translational potential. Apparently, the development of this class of lipids has been the focus of the research due to the promising therapeutic activity in animal disease models. Meanwhile, we begin to understand the factors determining the delivery efficiency such as the status of nanoparticles in the blood circulation and the impact of the major organs on the nanoparticles due to their anatomical structure and physiological function, tumor spatial and temporal heterogeneity, and conditions of tumor microenvironment. With this knowledge in hand, hundreds of rationally designed molecules including lipids and other macromolecules have been developed materialwise to improve the PK profile of the LNPs and transfection efficiency. All components are expected to contribute to the delivery efficiency according to their designs. Despite that these sophisticated components work wonderfully on their own, there was hardly any synergistic effect observed when combined together. Thus, in assembling all the components, it is important to ascertain that an optimization of formulation is conducted to achieve better delivery efficiency. It is envisaged that with the advent of novel lipids and formulation procedures, the seemingly insurmountable hurdle of gene therapy will be overcome in due course.

# PHOTOSENSITIVE LIPOSOMES AS POTENTIAL TARGETED THERAPEUTIC AGENTS

David H. Thompson, Pochi Shum, Oleg V. Gerasimov, and Marquita Qualls

*Department of Chemistry, Purdue University, West Lafayette, IN, USA*

## 4.1 INTRODUCTION

Many biological processes, including those involved in endosomal uptake, tumor growth and inflammation, occur in locally low pH or hypoxic environments [1,2]. In the case of rapidly growing tumors or inflammatory sites, the tissues also are often characterized by porous or poorly formed vasculature, providing limited nanoparticle access to these target tissues via the enhanced permeability and retention effect [3,4]. Taken together, these features have led to the development of a vast array of materials designs and delivery schemes to enhance the efficacy of therapeutic agents in acidic tumors and inflamed tissue. Herein we report recent efforts to utilize photochemical processes to initiate drug release from liposomal carrier systems in a controlled and potentially localized manner.

Liposomes are clinically proven, commercially successful nanoscale carrier systems for delivering high concentrations of small molecule agents such as doxorubicin [5], amphotericin B [6], verteporfin [7], cytarabin [8], and morphine [9]. Widespread clinical application of liposomes to other classes of drugs, however, has been hindered by both their limited tissue penetration [10,11] and their premature release of contents before they reach the target site. Acid-sensitive liposomes bearing targeting ligands can promote site-specific internalization via receptor-mediated

endocytosis [12] and exploit the time-dependent decrease in endosomal pH to promote escape of the liposomal contents into the cytosol [13–15]. They are particularly effective if they are designed with fusogenic lipids; however, if the formulation lacks an efficient triggering and endosomal escape mechanism, the drug cargo is destined for lysosomal degradation [16,17]. Bioactivation that promotes liposome–endosome membrane fusion is an effective strategy to promote cargo escape from both the liposomal and endosomal compartments. This is commonly achieved using phospholipid 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE), which adopts a bilayer state only at pH above the $pK_a$ of the phosphoethanolamine headgroup (i.e., >pH 8.0). At physiological pH and temperature, pure DOPE liposomes form an $H_{II}$ phase (i.e., an inverted micelle structure) that is "nonbilayer" and unable to retain the contents [18]. It is possible to increase the stability of DOPE-rich liposomes at physiological pH and temperature by formulating the liposome with stabilizing components, such as phosphoserine (PS) lipid [19,20], cholesterol hemisuccinate (CHEMS) [21,22], cleavable polyethylene glycol (PEG) lipids [23–26], or other cleavable polymers [27]. *In vitro* studies at neutral pH have shown that DOPE dispersions with CHEMS, PS, or PEG–vinyl ether–lipids [25,28,29] retain encapsulated fluorophores, suggesting that these liposomes should be structurally stable during circulation but remain responsive to low pH media. A family of PEG–vinyl ether–lipids recently reported by our group provide tunable pH-sensitivity over 10 orders of magnitude, making it now possible to engineer the liposomal release properties to display the desired release properties for a given target pH and timescale [30,31].

A greater control of acid-induced drug release may be achieved by photochemical acidification of target tissues. Light-activated dendrimeric photosensitizers [32], sensitizer-grafted polymer nanoparticles [33], gold nanorods [34], gold nanoshells [35], and liposomal-borne photosensitizers [16,36–38] have been described as agents to exert photodynamic effects on tumor cells. Liposomes offer many advantages over these systems as delivery vehicles because of the modularity of their design that offers a large aqueous compartment for cargo entrapment and a membrane shell that provides an adjustable surface-to-volume ratio as well as a site for hosting targeting ligands, fusogenic species, or other functional components. Thompson and coworkers have studied plasmenylcholines [39] and PEG–vinyl ether–lipids [25,28–31] for their potential as gene and drug delivery vehicles that are activated under low pH conditions and hydrolyzed via vinyl ether protonation reaction leading to cargo release from the carrier system [40]. It is well known that various onium salts are capable of producing Brønsted acids upon photo-induced intramolecular electron transfer bond cleavage [41–43]. One class of onium salts that exhibits this property is an anthracene-based photoacid generator (An-PAG), which liberates protons on exposure to UV illumination. Incorporation of lipid-modified An-PAG into liposomal bilayers, therefore, was anticipated to provide a means to stimulate contents release from these vehicles via acid-catalyzed vinyl ether hydrolysis in a light intensity-dependent manner. Incorporation of photosensitizers that can efficiently generate singlet oxygen within the vicinity of vinyl ether lipid membranes is another method of stimulating liposome release on aerobic irradiation.

This work describes the synthesis of a hexadecyl-modified An-PAG for use as a light-activated trigger, which will induce contents release from DOPE:lysoplasmenylcholine liposomes. We also describe the liposomes containing photosensitizers such as bacteriochlorophyll a (Bchl a) or aluminum phthalocyanine tetrasulfonate ($AlPcS_4^{4-}$). Finally, biodistribution of $AlPcS_4^{4-}$ -loaded liposomes in a murine tumor xenograft model is described.

## 4.2 EXPERIMENTAL PROCEDURES

### 4.2.1 Materials

DOPE and lysoplasmenylcholine (LysoPlsC) were obtained from Avanti Polar Lipids; all chemicals were obtained from Aldrich Chemical Company. Synthetic intermediates and final products were characterized by 300 MHz $^1$H NMR and MALDI MS using the Purdue University Center for Cancer Research's Interdepartmental NMR Facility and Campus-Wide Mass Spectrometry Center, respectively.

### 4.2.2 Synthesis of 1-Bromo-3-hexadecylthiobenzene (1)

To a solution of 1-bromo-3-thiophenol (2 ml, 19.4 mmol) in 20 ml of dry THF at 20°C was added NaH (20.0 mmol) with stirring under an Ar atmosphere. After gas evolution ceased (~10 min), 1-bromohexadecane (6.1 ml, 20 mmol) was added, along with a trace of $Bu_4NI$ as phase transfer catalyst, to the reaction mixture and heated at reflux for 20 h. The reaction mixture was then concentrated by rotary evaporation, the unreacted NaH destroyed by addition of $H_2O$ (5 ml), and the product extracted with $CH_2Cl_2$ (3 × 20 ml). The combined $CH_2Cl_2$ extracts were dried over $MgSO_4$ before filtration, evaporation, and purification by silica gel column chromatography with 95:5 hexane:EtOAc as eluent.

### 4.2.3 Synthesis of 9-[3-Hexadecylthiophenyl] anthracene (2)

Compound (**1**) (1 g, 2.42 mmol) was dissolved in 20 ml dry THF and Mg turnings (57.6 mg, 2.5 mmol) added along with a small $I_2$ crystal. The mixture was stirred under an Ar atmosphere for 10 min and then heated at reflux until all of the Mg had dissolved (about 1 h). Anthrone (580 mg, 3 mmol) dissolved in 10 ml dry benzene was then added all at once and the mixture stirred at 20°C for 18 h. The reaction was quenched by addition of 30% $H_2SO_4$ in water (10 ml) and the mixture extracted with $CHCl_3$ (3 × 20 ml). The extracts were combined, dried over $MgSO_4$, filtered, and the filtrate concentrated by rotary evaporation.

### 4.2.4 Synthesis of 9-[3-Hexadecyl-3'-cyanobenzylsulfonium] phenylanthracene Trifluoromethanesulfonate (C16-An-PAG) (3)

Compound (**2**) was dissolved in $CH_2Cl_2$ with 3-cyanobenzyl bromide. $Ag(OTf)_2$-dioxane complex was added to the reaction mixture as a solid and the reaction stirred

for 18 h at 20°C before filtration and evaporation of the solvent to give a crude residue that was purified by silica gel column chromatography using hexane:$Et_2O$ as eluent to give $C_{16}$-An-PAG.

### 4.2.5 Liposome Preparation

Stock solutions of DOPE (20 mg/ml), LysoPlsC (20 mg/ml), and $C_{16}$-An-PAG (4 mg/ml) were prepared in 95:5 benzene:MeOH and combined to give 10 mmol total of a 35:35:30 molar ratio of components. The lipid stock solutions were combined at the desired ratios and vortexed for 2 min before flash freezing in $LN_2$ for 3 min and lyophilization (15 h) to produce a powder. The lyophilized lipid mixtures were then hydrated in 1 ml of 100 mM $CaCl_2$ solution via 10 freeze–thaw–vortex cycles. The lipid suspension then was extruded 10 times through 100 nm polycarbonate membranes filters at 45°C. The liposome solution was passed through a Sephadex G-50 column equilibrated with a 150 mM NaCl solution to remove unentrapped $Ca^{2+}$ and the liposomes used immediately. Remote loading of doxorubicin was performed using the ammonium sulfate gradient method as described previously [37]. $AlPcS_4^{4-}$ was loaded using the passive entrapment method using DSPE–PEG2000–folate as targeting ligand as previously described [16].

### 4.2.6 Dynamic Light Scattering

Liposome sizes were measured by dynamic light scattering using a Coulter N4-Plus instrument and the distributions calculated using the manufacturer's supplied software. The experiments were run in triplicate and the average diameter reported.

### 4.2.7 Photoexcitation Method

Samples of the liposome solution (3 ml) were placed in a 1 cm path length quartz cuvette and placed in a temperature-controlled cuvette holder with stirring. A frequency-doubled continuous wave, mode-locked Nd:YAG laser provided 10 mW/s at 368 nm with a maximum energy of 1 mJ/pulse was used to activate the $C_{16}$-An-PAG-containing liposomes. Lenses were used to focus the beam to a typical spot size of 6 mm diameter. Bchl a- and $AlPcS_4^{4-}$ -containing liposomes were irradiated with an Al/Ga/As diode array laser emitting at 800 nm and coupled into a 1 mm optical fiber that was focused onto a temperature-controlled cuvette containing the stirred solution of liposomes.

### 4.2.8 Calcium Ion Release Assay

Absorption spectra were measured with a Hewlett-Packard 8453 UV–Vis spectrophotometer equipped with Chem Station software. Calcium-loaded liposomes were mixed with 2.85 ml Arsenazo III in 20 mM HEPES, pH 7.4. The absorption at 656 nm was measured and then Triton X-100 added to disrupt the liposomes and the absorption at 656 nm re-measured. The percent release was quantified using the

ratio method: % release $= 100 \times [(T - T_0)/(1 - T_0)]$, where $T =$ (fluorescence before Triton addition/fluorescence after Triton addition) at time $T$; $T_0 =$ fluorescence ratio at $T = 0$ min [44].

### 4.2.9 Negative Stain Transmission Electron Microscopy

A small drop of liposome solution was placed on a carbon-coated G-300 mesh copper grid and the excess liquid blotted away using filter paper after 1 min. A 1% solution of $UO_2OAc_2$ was then added for 1 min and the excess again removed using the filter paper. The sample was dried in a desiccator overnight before imaging on a Philips EM-400 transmission electron microscope operating at 80 kV accelerating voltage.

### 4.2.10 Animal Studies

Balb/c mice on folate-deficient diets were implanted with $5 \times 10^5$ M109 lung tumor cells via subcutaneous injection in a 100 μl volume with folate-deficient DMEM. The implants were allowed to grow for 3 week before imaging using a custom-built long-focal length microscope and camera system.

## 4.3 RESULTS AND DISCUSSION

### 4.3.1 DOPE:LysoPlsC Liposomes Using $C_{16}$-An-PAG as a Photosensitizer

***4.3.1.1 Synthesis of $C_{16}$-An-PAG.*** Indirect photoinitiation of liposomal content release was sought by using a membrane-anchored photoacid generator. We elected to prepare a hexadecyl-modified version of the anthracene-based photoacid generator [41–43] that transfers an excited $\pi^*$ electron from the anthracene moiety to the $\sigma^*$ lowest unoccupied molecular orbital localized on the phenylsulfonium moiety on irradiation at 368 nm, leading to bond rearrangement and production of a Brønsted acid. Previous work also suggests that the cyanobenzyl-substituted sulfonium salts are cleaved by a concerted electron transfer-bond fragmentation process (Scheme 4.1). The rate of C—S bond cleavage is exceedingly fast and dependent on several factors, including the thermodynamic stability of the cation radical–radical pair. Compound (**3**) was prepared as shown in Scheme 4.2 using a modified procedure reported for the methyl analog [41].

***4.3.1.2 Solution Acidification on Photolysis of $C_{16}$-An-PAG.*** $C_{16}$-An-PAG was dissolved in dry acetonitrile at a concentration of 1.5 mM and the absorption spectrum recorded, revealing peaks at 334, 350, 369, and 388 nm (Figure 4.1). Irradiation of this solution at 368 nm (35 mW/cm$^2$ illumination), with periodic sampling and analysis on 1:10 dilution into water, produced a rapid acidification over 2.5 pH units within 2 min at 37°C (Figure 4.2). The rapid acidification produced by this photoacid generator suggested that it could be useful for initiating acid-triggered release

**SCHEME 4.1** Photoinduced electron transfer process leading to the formation of triflic acid.

from appropriately designed pH-sensitive liposomes. Prior work by Thompson and coworkers [36,37] suggested that plasmenyl-type lipids could be used to effect rapid contents release from liposomes on acidification. This potential was tested using blends of LysoPlsC and DOPE.

***4.3.1.3 Light-Induced Liposome Leakage and Phase Change Using C16-An-PAG.*** The performance of 100 nm 35:35:30 DOPE:LysoPlsC:$C_{16}$-An-PAG liposomes was evaluated using a $Ca^{2+}$-Arsenazo III assay [45]. This formulation was selected because the $H_{II}$ phase of DOPE can be transformed into a stable lamellar phase by blending it with LysoPlsC, a pH-sensitive vinyl ether lipid of opposite curvature propensity that ultimately produces fatty acid degradation products upon acid-catalyzed hydrolysis in aerobic solution (Scheme 4.3). Cleavage of the LysoPlsC fraction within the liposome membrane causes a change in the intrinsic curvature of the fatty acid fragments, leading to a loss of $L_\alpha$ phase stability and a collapse of the liposome into the preferred $H_{II}$ phase of DOPE with concomitant release of the liposomal contents. Irradiation of the extruded, unbuffered liposome solution at 368 nm lead to 75% $Ca^{2+}$ release within 4 h, with accompanying change in the lipid morphology from spherical $L_\alpha$ phase liposomes to collapsed $H_{II}$ phase aggregates (Figure 4.3). Nonirradiated and irradiated buffered controls produced

**SCHEME 4.2** Synthesis pathway for $C_{16}$-An-PAG.

13% and 20% release, respectively, under the same illumination conditions. While the system containing $C_{16}$-An-PAG shows light-activated content release in an unbuffered condition, a faster release kinetics was desired. Therefore, we investigated another light-sensitive liposome systems.

**FIGURE 4.1** Absorption spectrum of $C_{16}$-An-PAG (**3**) in acetonitrile at 20°C.

**FIGURE 4.2** Rate of photochemical acidification produced by 1.5 mM (**3**) in acetonitrile at 37°C on illumination at 368 nm, 35 mW/cm$^2$.

### 4.3.2 PPlsC Liposomes Using Bchl a as a Photosensitizer

***4.3.2.1 Light-Induced Liposome Leakage and Phase Change Using Photosensitized Production of Singlet Oxygen ($^1O_2$).*** Prior work has shown that rapid calcein release occurs on photosensitized oxidation of palmitoylplasmenylcholine (PPlsC) [36,37] and dipalmitoylplasmenylcholine (DPPlsC) [46,47] liposomes at neutral pH using a variety of different chromophores. We evaluated the potential of PPlsC liposomes for drug delivery using Bchl a (Figure 4.4a) as a membrane-soluble

**SCHEME 4.3** Pathway for acid-catalyzed lysoplasmenylcholine (LysoPlsC) lipid hydrolysis. Aerobic oxidation of the initially formed fatty aldehyde hydrolysis product generates the corresponding fatty acid.

**FIGURE 4.3** Negative-stain TEM of 35:35:30 DOPE:LysoPlsC:$C_{16}$-An-PAG liposomes before (a) and 4 h after (b) irradiation at 368 nm.

photosensitizer. Since Bchl a is a near-infrared sensitizer that efficiently generates $^1O_2$ on aerobic irradiation, it was envisioned that rapid drug release should be possible on irradiation of drug-loaded PPlsC liposomes doped with Bchl a.

Liposome samples were prepared by evaporating a $CHCl_3$ solution of PPlsC and Bchl a into a thin film before hydrating the sample in ammonium citrate buffer and extruding it through 100 nm track-etch membranes. After buffer exchange to HEPES buffered saline via gel chromatography, doxorubicin was added and the solution incubated at 50°C for 10 min. Analysis of both the lipid and doxorubicin content indicated that a drug:lipid ratio of 0.085 was achieved, or approximately

**FIGURE 4.4** Photosensitizers used in this study. Bacteriochlorophyll a; (Bchl a, a) and chloroaluminum phthalocyaninetetrasulfonate ($AlPcS_4^{4-}$, b).

**FIGURE 4.5** Rate of doxorubicin release from remote-loaded 2-palmitoylplasmenylcholine (PPlsC) liposomes sensitized with Bchl a. [PPlsC] = 1.12 mM; [dihydrocholesterol] = 0.28 mM; [DOX] = 120 μM; [Bchl a] = 34 μM; 500 mW illumination at 800 nm, 38°C, 20 mM HEPES, 150 mM NaCl, pH 7.4.

2000 doxorubicin molecules per liposome. Illumination of this sample at 38°C with an Al/Ga/As diode laser emitting 800 nm excitation at 500 mW intensity led to complete doxorubicin release within 80 min (Figure 4.5). Since Bchl a is known to photobleach rapidly within the first 10 min of irradiation [37], the observed rate of drug release is actually a minimum drug efflux rate under these conditions since the extent of PPlsC photooxidation (estimated to be less than ~25%) is lower than desired to effect rapid release. The photoreleased doxorubicin remained cytotoxic within experimental error of the measurement [37].

### 4.3.3 Folate Receptor (FR)-Targeted DPPlsC Liposomes Using $AlPcS_4^{4-}$ as a Photosensitizer

***4.3.3.1 Rate of Liposome Internalization and Cargo Leakage Using the Folic Acid-Based Receptor-Mediated Endocytosis Pathway.*** Low and coworkers have demonstrated the utility of folate conjugates for targeting folate receptor (FR) positive tumor cells *in vitro* and *in vivo* [48]. Folate-modified liposomes have also been used to deliver cytosine arabinose to the cytoplasm of target cells [13]. In order to assess the kinetic timescale of this process, we loaded FR-targeted DPPlsC liposomes with propidium iodide (PI) as a probe that produces little fluorescence

**FIGURE 4.6** Rate of propidium iodide (PI) release from DPPlsC liposomes in KB cell culture with and without FR targeting. KB cells were treated with DPPlsC:PI liposomes containing 5% mPEG2000–DSPE (DPPlsC:PI, − folate) or 4.9% mPEG2000 and 0.1% folate–PEG3400–DSPE (DPPlsC:PI, + folate).

until it intercalates into DNA. Once inside the acidic endosomal pathway, we anticipated that the vinyl ether lipid would be hydrolyzed in a manner similar to Scheme 4.3 and the corresponding fatty aldehyde/fatty acid fragments would facilitate PI escape from the endosome and intercalate into cellular DNA. As the data in Figure 4.6 show, nearly 80% of the encapsulated PI is gradually released from FR-targeted liposomes over a 2–8 h timescale, whereas $\leq$14% PI staining of KB cells over the same time period when nontargeted DPPlsC:PI liposomes were used. These results show that the FR-targeted liposomes can deliver a cargo to FR-positive cells using receptor-mediated internalization.

***4.3.3.2 Pharmacokineticss and Biodistribution of FR-Targeted DPPlsC Liposomes Bearing $AlPcS_4^{4-}$ as a Photosensitizer Cargo.*** We sought to combine other water-soluble cargo, such as chloroaluminum phthalocyaninetetrasulfonate ($AlPcS_4^{4-}$) (Figure 4.4b), in the FR-targeted liposomes for labeling the cytoplasm of target cells for photodynamic therapy applications. We investigated the potential of this approach by loading FR-targeted DPPlsC liposomes with $AlPcS_4^{4-}$ at self-quenching concentrations so that the internalized sensitizer would be retained in a nonphotoactive state until reaching the target cell and escaping from the endosomes into the surrounding cytoplasm [16]. This photosensitizer was chosen because it is (i) much more photostable than Bchl a; (ii) rapidly cleared from blood in its free form (i.e., will be rapidly excreted if lost from the liposomal carrier during systemic circulation, thereby limiting the dermatologic sensitivity that is commonly observed for hematoporphyrin derivative formulations); (iii) capable of triggering efflux from DPPlsC liposomes as shown in Scheme 4.4; and (iv) highly water soluble, thus

**SCHEME 4.4** Pathway for photooxidative cleavage of the divinyl ether lipid, diplasmenylcholine (DPPlsC). Stepwise addition of $^1O_2$ to the electron rich vinyl ether bond leads to the thermally unstable, putative bis-dioxetane intermediate shown in brackets. Initial fragmentation of this species produces 2 equiv. of glycerophosphocholine bisformate ester that are rapidly hydrolyzed to formate and glycerophosphocholine. Aerobic oxidation of the initially formed fatty aldehyde photolysis product generates the corresponding fatty acid.

potentially limiting its volume of distribution *in vivo* to only those cells that have internalized the $AlPcS_4^{4-}$-loaded liposomes, such as FR-positive tumor cell targets and nontarget cells of the reticuloendothelial system that commonly scavenge nanoparticulate carriers (i.e., macrophages within the liver and spleen).

As the data in Figure 4.7 show, substantial $AlPcS_4^{4-}$ fluorescence appears rapidly in the 1–2 mm subcutaneous M109 FR-positive xenograft tumors within 2 h compared to nontarget surrounding skin tissue. Approximately 35% of this tumor-localized $AlPcS_4^{4-}$ fluorescence is lost within 5 h, with slow depletion of an additional 12% occurring over the next 67 h, to give a total retained dose of ~53% 72 h after injection (<0.3% of skin-localized dose was detectable in healthy skin at this time point). Since the $AlPcS_4^{4-}$ cargo was encapsulated at self-quenching concentrations, we cannot entirely exclude the possibility that normal skin was capable of harboring liposomes but not stimulating $AlPcS_4^{4-}$ release as in FR-targeted KB cells [16]. However, in the absence of specific adhesion mechanisms that would promote liposome accumulation in vital skin, we infer from these findings that the low observed $AlPcS_4^{4-}$ fluorescence is due to low levels of skin-accumulated $AlPcS_4^{4-}$. This is an important advantage since one of the most common side effects of the hydrophobic photosensitizers typically used in photodynamic therapy is cutaneous photosensitivity. The low levels of skin-accumulated $AlPcS_4^{4-}$ fluorescence suggest that this issue may not be as problematic as other hydrophobic photosensitizers that display a long persistence in skin.

The biodistribution of $AlPcS_4^{4-}$ in the mouse model was evaluated 2 h after infusion of FR-targeted DPPlsC/$AlPcS_4^{4-}$ liposomes via tail vein injection (Figure 4.8). Liver, tumor, spleen, and kidney were found to have the highest $AlPcS_4^{4-}$

**FIGURE 4.7** Fluorescence kinetics of FR-targeted DPPlsC liposomes loaded with $AlPcS_4^{4-}$ in a 1–2 mm subcutaneous folate-receptor positive M109 FR-positive tumor murine xenograft relative to nontarget skin tissue. DPPlsC:Chol:mPEG2000–DSPE:folate–PEG3400–DSPE liposomes (59.9:35:5:0.1) containing 9.8 μM $AlPcS_4^{4-}$ were injected via tail vein and imaged using a home-built fluorescence imaging microscope at the times indicated.

**FIGURE 4.8** Biodistribution of $AlPcS_4^{4-}$ fluorescence 48 h after infusion of FR-targeted DPPlsC/$AlPcS_4^{4-}$ liposomes as described in Figure 4.7.

fluorescence levels, with liver and tumor displaying 2–3 times higher accumulation than spleen and kidney over this time period. Extensive uptake by liver and spleen is commonly observed for nanoparticles [8], as is kidney uptake due to scavenger receptors for folic acid in these tissues [49]. It is noteworthy that the levels present in tumor were comparatively high, however, additional experiments are needed to determine their specific localization (i.e., deeply penetrated into tumor tissue or near the extravasation site) and whether they have been internalized by FR-positive tumor cells or are simply adherent to the surface of the cells.

## 4.4 CONCLUSIONS

Several different photochemical schemes were developed and employed using a variety of vinyl ether-based liposome systems. Photoacid generation using (**3**), a membrane-immobilized, anthracene-based sulfonium salt, induced cargo release on the hours timescale even though the rate of $H^+$ release occurs on the minutes timescale. This suggests that, in spite of membrane localization of the $C_{16}$-An-PAG derivative, the protons are released into bulk solution rather than remain associated with the membrane where vinyl ether hydrolysis must occur. Photooxidative drug release was also demonstrated on the minutes timescale using the near infrared photosensitizer, Bchl a. FR targeting of liposomal PI and $AlPcS_4^{4-}$ to FR-positive KB cells was also demonstrated in cell culture and *in vivo*, with the latter displaying promising characteristics with regard to tumor:nontarget tissue distributions. Taken together, these results suggest that it is possible to design light-responsive liposomes to provide a level of functional control and reaction kinetics that are difficult to achieve with other triggering modalities.

## 4.5 PROSPECTS FOR LIGHT-ACTIVATED LIPOSOMAL DRUG DELIVERY

Our findings suggest that opportunities remain for the development of effective phototherapeutic strategies using specific targeting ligands that can selectively deliver cytotoxic agents to tumor cells *in vivo*. Major challenges remain, however, in the development of (i) chromophores that can be activated in the near infrared to elicit their action in the absence of oxygen, since most solid tumors have regions that are substantially hypoxic; (ii) strategies that display large bystander effects due to tumor heterogeneity; and (iii) techniques that enable the real-time assessment of therapeutic progress so that the treatment can be modulated as required for individual patient outcome.

### Acknowledgments

We gratefully acknowledge financial support by National Institutes of Health (GM087016) and the 21st Century Research and Technology Fund of Indiana. We would like to thank the Purdue University Center for Cancer Research

Interdepartmental NMR Facilities and Campus-Wide Mass Spectrometry Center (supported by NCI CCSG CA23168 to Purdue University Center for Cancer Research) for their materials characterization support. We also thank Mike Kennedy, Karim Jallad, Dor Ben-Amotz, and Phil Low for fruitful discussions.

# MULTIFUNCTIONAL DENDRITIC NANOCARRIERS: THE ARCHITECTURE AND APPLICATIONS IN TARGETED DRUG DELIVERY

Ryan M. Pearson, Jin Woo Bae, and Seungpyo Hong

*Department of Biopharmaceutical Sciences, College of Pharmacy, University of Illinois, Chicago, IL, USA*

## 5.1 RECENT ADVANCES IN DENDRITIC NANOMATERIALS

Dendrimers are hyperbranched, monodispersed macromolecules with chemically well-defined structures. Synthesized by either the convergent or divergent method, a dendrimer consists of three functional domains (core, interior, and periphery) as shown in Figure 5.1. Each domain of a dendrimer can be tailored to precisely and easily control its molecular weight, size (hydrodynamic radius), and surface charge and functionality [1]. The highly controllable physical properties of dendrimers enable the fine-tuning of their biological properties, such as cytotoxicity, biodistribution, and intracellular uptake/trafficking/fate [2–4]. Furthermore, the large number of the surface groups also allows facile multifunctionalization of dendrimers through incorporation of a variety of functional molecules such as therapeutic and diagnostic moieties. The high deformability and the capability to precisely control their surface functional groups make dendrimers ideally suited for mediating strong multivalent interactions between ligands and receptors [5–7]. These unique properties of dendrimers have led these nanomaterials to become one of the most promising platforms for targeted drug delivery. Over the past two

decades, significant progress has been made toward the development of dendrimer-based nanotherapeutics for cancer treatments, as highlighted in several recent reviews [8–12]. Although dendrimers have shown great promise in improving cancer treatments and diagnoses, these materials have some limitations that may negatively impact the outcomes of clinical trials and hinder their advancement to the clinic. The drawbacks include complex, multistep synthetic procedures that present scalability issues and limited options for carrying drug molecules, that is, covalent conjugation. Conjugation of drug molecules to the dendrimer often results in low drug payload, in addition to introducing unnecessary chemical modifications to drug molecules [1,13]. Furthermore, extensive surface conjugation with many functional molecules often induces the deterioration of the material properties and structural regularity of the dendrimer [5].

In parallel with the progress of dendrimers, dendron-based nanomaterials have also attracted a great deal of scientific interests due to their capability to hybridize the multifunctional and multivalent properties of dendrimers with various organic and inorganic materials [14]. Dendrons are monodisperse wedge-shaped, hyperbranched sections that comprise dendrimers. Their unique molecular architecture enables chemical modifications of the focal point and/or the periphery, allowing a multitude of complex structures to be realized [14,15]. The use of dendrons for cancer treatments has not yet reached the same level as dendrimers; however, because of their versatility and modular characteristics, they have rapidly emerged as a potential targeted drug delivery platform. In particular, amphiphilic dendrons capable of self-assembly can be engineered to form dendron-based copolymer micelles in aqueous solutions at polymer concentrations higher than the critical micelle concentration (CMC). These micelles can carry significantly higher numbers of drug molecules within their core than dendrimers, while maintaining multiple functional groups on their surface available for chemical modifications [16–18].

However, another level of structural complexity arises from their nonunimolecular structure. Optimization of each structural component is thus necessary because the morphology of self-assembled structures is difficult to predict and often has a marked effect on its biological properties [19].

In this chapter, we highlight promising dendritic systems and discuss their limitations and recent approaches to overcome those drawbacks. The discussion progresses through sections describing important architectural parameters used to rationally design various dendritic materials. Dendritic structure-related toxicity, biodistribution, cellular uptake, and multivalency are also described in detail. Additionally, we discuss through examples how dendrimers and dendrons have been designed and used as targeted drug delivery vehicles for cancer diagnosis and treatments in particular. We anticipate that dendritic materials possessing multifunctional architectures will have a significant impact on the way by which cancer is prevented, diagnosed, treated, and ultimately cured in the future.

## 5.2 EFFECTS OF DENDRITIC ARCHITECTURES ON BIOLOGICAL SYSTEMS

Many types of dendritic macromolecules have been developed spanning various fields since 1978 [20,21]. However, the clinical translation of these exciting materials has been disappointingly slow due to the issues related to nonspecific toxicity and biodistribution. To date, VivaGel$^{TM}$, a topically applied vaginal microbicide [22], is the only dendrimer-based product that has been approved by the FDA for the clinical trials. Other promising dendrimer-based therapeutics that are in preparation for clinical trials include Gadomer-17, a magnetic resonance imaging (MRI) contrast agent [23], and a colony-stimulating factor 1 receptor (CSF1R)-targeted dendrimer for the treatment of rheumatoid arthritis [24]. To design highly effective dendrimers, a number of parameters must be considered and optimized. In this section, we discuss how architectural parameters, such as generation (size), surface charge, and chemical composition, can be balanced to control dendrimer-related toxicity and biodistribution, and to achieve highly specific biological interactions.

### 5.2.1 Structure-Related Toxicity and Biodistribution

A review by Duncan and Izzo described the biocompatibility and structure-related toxicity of dendrimers with various backbone structures [25]. The most important factors found to affect the biocompatibility of dendrimers were surface charges and generation. Malik et al. studied the effects that dendrimer surface functionality and generation had on hemolysis and cell morphology [26]. Amine-terminated poly(amidoamine) (PAMAM) and poly(propylenimine) (PPI) dendrimers exhibited generation-dependent toxicity. The increased toxicity of higher generation dendrimers has been attributed to (i) the large number of surface groups at the same molar concentration, that is, greater charge density; and (ii) the increased radius of curvature, which increases the contact area at the dendrimer–cell

membrane interface [2]. The toxicity by the amine-terminated (positively charged) dendrimers can be substantially reduced by acetylation, carboxylation, or PEGylation (covering the surface with a hydrophilic nonfouling layer of poly (ethylene glycol) (PEG)) of the dendrimer surfaces [27]. Chen et al. modified melamine-based dendrimers to amine, guanidine, carboxylate, sulfonate, phosphate, and PEG-terminated ones [28]. The dendrimers with amine groups exhibited significantly higher cytotoxicity than all other types of dendrimers, whereas PEGylated dendrimers had significantly reduced cytotoxicity after 24 h incubation at a concentration of 10 mg/ml.

Amine-terminated dendrimers are generally known to cause cytotoxicity through destabilization of cell membranes because of the electrostatic interactions, but the underlying mechanism has not been fully understood. To study these nanoscale interactions between PAMAM dendrimers and lipid bilayers, Hong et al. used atomic force microscopy (AFM), a series of enzymatic assays, a fluorescence-activated cell sorter (FACS), and fluorescence microscopy [2,3,29]. For AFM observations *in situ*, 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC) was prepared as supported lipid bilayers and subsequently treated with various PAMAM dendrimers. It was observed that cationic dendrimers induced the formation of nanoscale holes in the supported DMPC lipid bilayers in a size-dependent manner. Generation 7 (G7) PAMAM dendrimers were able to initiate hole formation but G5 PAMAM dendrimers could only expand the size of pre-existing defects. Leakage of cytosolic proteins luciferase (Luc) and lactate-dehydrogenase (LDH) from KB and Rat2 cells also demonstrated that PAMAM dendrimers permeabilized cell membranes with size dependency, that is, G7 induced more enzyme leakage than G5 [2]. The membrane integrity was restored 2 h after the removal of G5 PAMAM dendrimers from the incubation medium, indicating the dendrimer-induced membrane permeabilization was reversible. On the other hand, acetamide-terminated (charge neutral) dendrimers neither caused defects nor induced enzyme leakage at the concentrations tested with either generation. This study provided direct evidence that amine-terminated PAMAM dendrimers could disrupt lipid bilayers in a concentration- and generation-dependent manner.

Given that the high toxicity and poor degradability of PAMAM and PPI dendrimers hinder their translation into clinical applications, several new dendrimers have been synthesized and tested as alternatives. For example, hydroxyl-terminated, biodegradable polyester dendrimers based on a 2,2-bis(hydroxymethyl) propionic acid (polyester) backbone were synthesized [30,31]. While $IC_{50}$ (half maximal inhibitory concentration) of amine-terminated dendrimers have been reported as low as 50 μg/ml after 72 h incubation [26], polyester dendrimers have shown much less toxicity, where 60% of the growth rate of B16F10 cells was maintained at a concentration of 20 mg/ml after 48 h incubation [32]. The relatively low toxicity of polyester dendrimers is attributed to hydroxyl groups on the surface, which likely decreased nonspecific cellular interactions [33]. To address the nondegradability of dendrimers, stimuli-responsive functional groups have been incorporated into the dendrimer structure that respond to enzymes, light, reduction, or pH to ensure degradation [34].

Biodistribution reflects the *in vivo* fate of dendrimers. The biodistribution of dendrimers has been traditionally studied in the context of diagnostic applications, since their multiple surface functional groups offer conjugation sites to create multimodal imaging probes [35]. As observed in numerous *in vitro* studies, the generation and surface properties of dendrimers largely affects their biodistribution profiles. Margerum et al. first reported a generation-dependent biodistribution of PAMAM dendrimers, radiolabeled with gadolinium (Gd) using MRI [36]. G5 dendrimers accumulated more preferentially in the liver after 7 days as compared to lower generations G2–4. However, the biodistribution of these Gd-dendrimer chelates cannot be universally applied to other dendrimers because the Gd ions may influence the molecular weight and surface composition. $^{125}$I-labeled cationic and anionic PAMAM dendrimers have shown structure and size dependent biodistribution profiles [26]. Anionic PAMAM dendrimers administered intravenously to Wistar rats at a concentration of 10 μg/ml showed a 10- to 20-fold longer circulation time than cationic PAMAM dendrimers. It was also noted that lower generation dendrimers exhibited longer circulation times. Both anionic and cationic dendrimers were found to primarily accumulate in the liver (30–90%) 1 h after administration, indicating that the dendrimer surface groups need to be modified to avoid hepatic uptake if tumor targeting is intended. In this regard, PEGylation has been exploited as a means to enhance the blood circulation half-life and decrease opsonization [37]. Kojima et al. have shown using lysine-modified PEGylated PAMAM dendrimers that the increased circulation time was most probably attributable to a large increase in molecular weight and full surface coverage of PEG on the dendrimer [38].

As for dendrons and dendron-based hybrid materials, it is difficult to make a general conclusion with respect to structure-related toxicity and biodistribution due to a large variety of the possible structures. For this reason, each type of dendron should be evaluated independently to ensure that it elicits appropriate biological responses. Because of the versatility and uniqueness of the structures that can be created, a vast number of different architectures have been synthesized [14]. To date, there have been only a few biodistribution studies of dendron-based materials. $^{111}$In-labeled linear dendritic block-copolymer micelles comprised of a hydrophobic polypeptide (β-benzyl-L-aspartate) conjugated to a carboxyl-terminated PEGylated G4 polyester dendron were evaluated in tumor-bearing nude mice [39]. The micelles were shown to accumulate to all vessel-rich organs initially, and most of the micelles were cleared from the body by day 5. Gillies et al. synthesized polyester "bow-tie" hybrid dendrimers comprised of two asymmetric polyester dendrons and evaluated their biodistribution profiles in both tumored and nontumored mice [40]. Polymers with molecular weights of 40,000 Da or greater were found to have significantly enhanced circulation times compared to lower molecular weight polymers. The degree of branching was found to play a role in determining circulation times as well. Higher generation bow-tie dendrimers circulated for a longer time and showed relatively less renal clearance, likely due to decreased molecular flexibility and difficulty to pass glomerular filtration [40].

### 5.2.2 Mechanisms for Cell Entry of Dendrimers

The ability of dendrimers to interact with cells and cross cell membranes is critical to the effective delivery of therapeutic and diagnostic payloads. Multiple pathways have been proposed as potential mechanisms of cell entry of dendrimers, which are largely affected by molecular size, shape, charge, and surface chemistry [41]. It is particularly important to understand the cellular uptake, intracellular trafficking, and fate of dendrimers when designing novel nanocarriers with subcellular targeting capabilities [42]. Many groups have revealed various mechanisms of PAMAM dendrimer internalization as summarized in Table 5.1. Cationic PAMAM dendrimers have high affinities for plasma membranes that are negatively charged because of proteoglycans and phospholipids, resulting in a nonspecific adsorptive uptake mechanism. Therefore, modification of the dendrimer surface is necessary to achieve fine control over their cellular interactions.

The mechanism by which dendrimers are internalized into cells is a subject of considerable debate. For example, in Caco-2 cells, cationic PAMAM and carboxylated PAMAM dendrimers were shown to internalize by a clathrin-dependent endocytosis mechanism [43]. These results were further confirmed in studies performed using HeLa cells, where cationic PAMAM and partially acetylated PAMAM dendrimers were internalized via both clathrin-mediated endocytosis and macropinocytosis [44]. In other studies, carboxylated PAMAM dendrimers were internalized into A549 lung epithelial cells by a caveolae-mediated pathway, and neutral or cationic PAMAM dendrimers were taken up by nonclathrin/noncaveolae-mediated mechanisms [45]. Recently, Hong et al. reported a systematic study regarding the cellular internalization mechanisms of G7 PAMAM dendrimers with various surface charges such as amine, acetyl, and carboxyl groups [3]. Fluorescently labeled cholera-toxin subunit B (CTB), transferrin (Tf), and ganglioside $GM_1$-pyrene were employed as endocytic markers to be co-incubated with PAMAM dendrimers. G7 PAMAM dendrimers were found to co-localize with CTB in KB and Rat2 cells whereas acetylated and carboxylated dendrimers did not interact with the cells. Co-localization with CTB is generally taken as indirect evidence for $GM_1$ interaction and a caveolae-mediated uptake mechanism since CTB does not internalize without $GM_1$. To further assess the role that $GM_1$ may have in facilitating the uptake of G7 PAMAM dendrimers, similar experiments were performed using C6 cells, which are $GM_1$ deficient. Interestingly, C6 cells that lack $GM_1$ still allowed G7 PAMAM dendrimers to be internalized, indicating that caveolae-mediated endocytosis is not the only mechanism for dendrimer internalization. Additionally, G7 PAMAM dendrimers were internalized into cells even at 4°C, suggesting that the internalization mechanism may not be energy-dependent. This study, together with the series of publications [2,3,29], presented strong evidence that nanoscale hole formation is a mechanism of cellular internalization for cationic dendrimers, in addition to other endocytotic mechanisms. Results of these studies strongly suggest that the mechanism of dendrimer internalization is multifaceted and depends on numerous factors including material properties (i.e., charge, generation), concentration, and cell type. It is most likely

that multiple cellular uptake mechanisms are involved and govern the cellular uptake of dendrimers.

### 5.2.3 Multivalent Interactions

Multivalent interactions, which naturally occur in many biological systems, are characterized by simultaneous binding of multiple ligands to multiple receptors [46,47]. These interactions are critical to many pathological and physiological processes and can confer several advantages, such as improved and tight binding through amplification of an existing interaction, increased specificity of binding, efficient signaling communication with cells, and prevention of undesired interactions [46,48,49]. Therefore, understanding of multivalent ligand–receptor interactions is important for designing dendritic nanocarriers that are highly specific to target cells. Several possible mechanisms for multivalent interactions have been proposed. These include the chelate effect, subsite binding, steric stabilization, statistical rebinding, and receptor clustering [46,50]. In particular, the statistical effect (rebinding by a high local concentration of ligands) and the multivalent effect (multivalent binding between multiple ligands and receptors, which may lead to receptor clustering) have been mainly investigated [51,52]. Figure 5.2 depicts the two major mechanisms.

Early studies of multivalent targeting were primarily performed to understand carbohydrate–protein interactions and to gain insight into how proteins present on

**FIGURE 5.2** Schematic representation of multivalent binding of ligand-conjugated dendrimers to target cell surfaces. Dendrimers functionalized with multiple copies of targeting ligands can bind to specific receptors overexpressed on cell surfaces via multivalent interactions. Multiple ligand presentation on the dendrimer surface can lead to the statistical binding effect if their complementary receptors are not clustered on the cell surface. Simultaneous binding of multiple ligands to multiple receptors is responsible for the multivalent effect, which can affect signaling functions of receptors.

cell surfaces can recognize carbohydrates. These studies focused on interactions of mannoside-concanavalin A (Con A) with pea lectin [53], sialic acid with CTB with heat labile enterotoxin of *E. coli* [54], sialic acid with virus hemagglutinin [55], lactose with CTB [56], and hyaluronan with CD44 [57]. Carbohydrate–protein interactions are dependent upon multiple factors including hydrogen bonding and hydrophobic interactions. Additionally, these interactions are known to be involved in a number of important biological phenomena such as cell–cell interactions, antibody–antigen interactions, and viral infection by strengthening their interactions through receptor clustering [58–60]. Since then, many researchers have attempted to establish a rational dendritic design that captures the essence of the effective multivalent binding observed between carbohydrates and proteins.

Some of the studies to understand how dendritic structures may affect multivalent interactions were performed using glycodendrimers exploiting the well-known carbohydrate–protein interactions. Glycodendrimers with 16 mannoside residues possess much higher binding avidities toward Con A and pea lectins compared to single carbohydrate residues [53]. However, fully mannose-substituted larger glycodendrimers (36-mer with three mannose residues per arm) did not achieve a significant increase in binding. It appeared to be a result of steric hindrance of neighboring carbohydrates and/or saturation of binding sites available on the cell surface [61]. It implies that there should be an optimal number of ligands that can participate in multivalent interactions. Andre et al. further supported the notion of an optimal ligand number using lactose-functionalized G5 PAMAM dendrimers [62]. These dendrimers displayed an optimal level of carbohydrate density for effective multivalent interactions with different proteins. Similar results have been reported elsewhere [63–67], providing additional evidence that multivalent binding is highly dependent on the number of surface ligands.

Further modifications to the dendrimer structure were shown to enhance the multivalent binding events of carbohydrates. Simple modifications of the dendrimer surface with short and long chemical linkers increased the conformational flexibility of carbohydrates bound to dendrimers, which might increase the mobility of ligands and probability of binding to its appropriate receptor. Flexible linkers can facilitate optimal geometric orientation of ligands toward binding sites in a thermodynamically favorable manner, compared to rigid linkers [68,69]. Although the effect of chemical nature and the length of linkers on multivalent interactions have not been fully understood, the use of a PEG linker has proven effective in inducing efficient multivalent binding [70,71].

In addition to the number and the flexibility of bound carbohydrates, a variety of architectural parameters such as size, shape, and density of binding elements can affect multivalent interactions. Gestwicki et al. explored the effect of ligand architecture on receptor binding and clustering by synthesizing a series of 28 mannose-containing ligands that varied in size, shape, and density [72]. These ligands were derived from five structurally different classes of materials (low-molecular weight compound, PAMAM dendrimer, bovine serum albumin, linear, and polydisperse polymers). The multivalent binding modes of the various mannosylated ligands with the lectin Con A were explored using high-throughput assays. As Con A can be clustered by

multivalent ligands (e.g., mannose), Con A is an excellent model protein for examining different aspects of multivalent binding, such as the number of clustered receptors, receptor-clustering rate, and receptor proximity. It was found that ligand architectures resulted in different degrees of Con A inhibition and clustering. Although dendrimers did not generate the most effective ligand architecture for either Con A inhibition or clustering, it was shown that the dendrimer with higher mannose content was a more effective inhibitor of Con A than the dendrimer with a lower mannose content. In addition, the rapid receptor-clustering rate from the highly functionalized, large dendrimers was observed. However, further investigation is necessary to determine how architectural parameters influence multivalent binding modes in other systems.

On the basis of these initial efforts on multivalent targeting, many researchers have sought ways to treat and detect cancer effectively by ligand-conjugated dendritic materials. There are several studies supporting that appropriate presentation of tumor targeting ligands on dendritic surfaces enables the nanocarriers to achieve high binding avidity and specificity toward cancer cells [5,7,73–76]. Hong et al. first reported a quantitative and systematic study of the multivalent effect using G5 PAMAM dendrimers with different numbers of folate as a targeting ligand [5]. The measurements using surface plasmon resonance (SPR) revealed that increasing the number of folate per dendrimer can dramatically enhance the binding avidity toward folate receptors (FRs) up to 170,000-fold, compared to free folic acid (FA). However, high-folate conjugation (over $\sim$7 folate molecules per dendrimer) compromised the material properties of the dendrimer (increased polydispersity index (PDI) and decreased solubility). Saturation behaviors were observed in cell-level experiments using FACS. When the number of folate per dendrimer was increased, dendrimer binding to FR-overexpressing KB cells was increased; however, the improvement became marginal when more than seven folates were conjugated to a dendrimer molecule. This study clearly demonstrated that an optimal number of targeting agents (five folate molecules per dendrimer in this particular case) needs to be identified, in order to achieve the maximal binding avidity without compromising materials properties.

Despite a number of studies on multivalent interactions, it is still unclear which architectural factors are most crucial to designing novel dendritic structures. Obviously, ligand number and flexibility of ligand presentation should be considered in optimizing multivalent interactions; however, evaluation of dendritic constructs with multivalent targeting should vary on a case-by-case basis depending on the types of ligands and target receptors.

## 5.3 FUNCTIONALIZATION OF DENDRITIC STRUCTURES VIA SURFACE MODIFICATION

Controlling biological properties of dendritic materials via surface modification has been well established as an effective method to create multifunctional architectures of dendritic materials. Depending on the purpose of each study, various molecules have been covalently conjugated to dendrimers at varying numbers and densities. To date, a variety of conjugation methods have been reported to introduce drugs,

**FIGURE 5.3** Various surface modification methods of amine-terminated dendrimers. Starting from amine-terminated dendrimers, many types of surface functional groups can be easily introduced to dendrimers for further applications.

hydrophilic spacers, targeting molecules, and imaging modalities onto dendritic surfaces. Although the conjugation chemistry depends on the molecular functionality to be linked, ideally the method for surface modification should be simple and well defined without causing any loss of inherent reactant properties. Various reagents are commercially available for chemical coupling of molecules and dendritic materials. Figure 5.3 depicts frequently used methods for surface modification of amine-terminated dendrimers such as PAMAM, PLL, and PPI dendrimers. These strategies allow conjugation of a variety of functional groups onto the dendrimer surface, enabling further modification of dendrimers. As previously mentioned, PEGylation is one of the effective surface modification methods that can increase the blood circulation time of dendritic materials through prevention of nonspecific interactions with biological substances. In general, two types of PEGylation strategies have been widely adopted. *N*-Hydroxysuccinimide (NHS)- and *p*-nitrophenyl chloroformate (*p*-NPC)-based chemistries have been commonly used for water- and organic solvent-based reactions, respectively. Zhu et al. compared the PEGylation efficiency of G3 PAMAM dendrimers using these two strategies [77]. Dendrimers PEGylated using *p*-NPC-PEG achieved significantly higher levels of PEGylation compared to those using PEG–NHS [78].

## 5.4 DENDRIMER-BASED THERAPEUTIC AND DIAGNOSTIC APPROACHES

Various dendrimer-based nanocarriers have been extensively exploited for effective cancer treatment. Table 5.2 lists the most recent achievements in cancer therapy and diagnosis. The surface properties of the dendrimers were rationally modified with bioactive entities (drugs, genes, targeting ligands, and imaging agents) and their *in vivo* efficacy was studied. In this section, we discuss how dendritic properties affect *in vivo* efficacy using examples in three major delivery applications: anticancer drugs, genes, and imaging agents.

**TABLE 5.2 Recent Progress in Cancer Research Using Various Dendrimers**

| Purpose of Study | Dendritic Materials | Therapeutics or Diagnostics | References |
|---|---|---|---|
| Folate-mediated targeting of conjugated drugs | PAMAM dendrimer | Methotrexate, paclitaxel | [86,112] |
| Tumor accumulation by different PEGylation degrees and drug conjugation style | PAMAM dendrimer | Doxorubicin | [77] |
| Convection enhanced delivery of boronated dendrimer-epidermal growth factor bioconjugate for boron neutron capture therapy | PAMAM dendrimer | Boron | [122] |
| Folate-mediated targeting of drug encapsulated PEG-dendrimer | PAMAM dendrimer | 5-Fluorouracil | [114] |
| Targeted siRNA delivery of cRGD conjugated dendrimers through spheroid model of malignant glioma | PAMAM dendrimer | siRNA | [123] |
| *In vivo* tumor imaging by activatable cell penetrating peptide-coated dendrimer labeled with Cy5 and gadolinium | PAMAM dendrimer | Cy5, gadolinium | [124] |
| Folate-mediated *in vivo* tumor imaging using gadolinium-conjugated dendrimer | PAMAM dendrimer | Gadolinium | [125] |
| *In vivo* imaging using multimodal and multicolor nanoprobes | PAMAM dendrimer | $^{111}$In, Cy5, Alexa 660, 680, 700, and 750 | [126] |
| Systemic antiangiogenic activity of dendrimer itself | PLL dendrimer | — | [127] |
| Delivery of anticancer drug using PEG-dendrimer | PLL dendrimer | Camptothecin | [113] |
| *In vivo* tumor imaging using gadolinium-conjugated dendrimer | PLL dendrimer | Gadolinium | [128] |
| Targeted siRNA delivery using cross linked PEG-dendrimers with LHRH peptide | PPI dendrimer | siRNA | [129] |
| *In vivo* visualization of gene transfer mediated by systemic injection of dendrimer-pDNA complex | PPI dendrimer | pDNA | [130] |
| *In vivo* imaging and biodistribution of radiolabeled dendrimer | PE dendrimer | $^{99m}$Tc | [131] |
| Biodistribution of drug-conjugated dendrimer and comparison with drug-loaded liposome | PE dendrimer | Doxorubicin | [132] |
| Noninvasive imaging of angiogenesis using PEG-dendrimer coated with cRGD | PE dendrimer | $^{76}$Br | [133] |
| Targeting of glial tumor and enhanced permeability across blood brain barrier using glucosylated dendrimer | PEPE dendrimers | Methotrexate | [134] |
| Photodynamic therapy using dendrimer phthalocyanine-encapsulated polymeric micelles | PAE dendrimer | Phthalocyanine | [135] |
| *In vivo* efficacy of conjugated drugs using PEG-dendrimer | PEA dendrimer | Doxorubicin | [136] |

PAMAM, polyamidoamine; PLL, poly(L-lysine); PPI, poly(propylenimine); PE, polyester; PEPE, polyether-copolyester; PAE, poly(acryl ether); PEA, poly(ester-amide); LHRH, luteinizing hormone-releasing hormone; cRGD, cyclic (Arg–Gly–Asp) peptide.

### 5.4.1 Delivery of Anticancer Drugs

Dendrimers have been investigated on numerous occasions for the delivery of small molecule anticancer drugs. Through implementation of rational design parameters, their efficacy has been reported to be superior to traditional chemotherapeutics. There are two major methods utilized to incorporate anticancer drugs with the dendrimer [18]. The first method is through encapsulation [79–81], where drugs noncovalently interact with the nonpolar interior core of the dendrimer forming a host-guest complex; and the second, drugs can be covalently attached to one of the many surface groups at the dendrimer periphery [82–84].

As drug encapsulation into dendrimers has several limitations such as low drug loading and uncontrollable drug release, conjugation of therapeutics to dendrimers has been preferred and well established as a means to increase drug solubility, circulating time, and accumulation in tumor tissue *in vivo* [9]. However, it should be noted that there is a limit to the number of molecules that can be conjugated to the surface of dendrimers to maintain structural regularity and solubility [5]. Ideal dendrimer-based carriers should mitigate any surface charges that cause cytotoxicity, possess an imaging capability for *in vivo* visualization, and carry multiple synergistic bioactive compounds to treat the target disease. Figure 5.4 illustrates a set of dendrimer-based

**FIGURE 5.4** Recently studied dendrimer-based anticancer drug delivery systems. (a) PAMAM dendrimer–folic acid–methotrexate [111], (b) PAMAM dendrimer–folic acid–paclitaxel–FITC [112], (c) camptothecin conjugated PLL dendrimer–PEG [113], (d) 5-fluorouracil encapsulated PAMAM dendrimer–PEG–folic acid [114], (e) phthalocyanine dendrimer encapsulated PEG–PLL micelle [115].

**BOX 5.1 IMPORTANT DESIGN CONSIDERATIONS FOR THE DEVELOPMENT OF DENDRIMER-BASED THERAPEUTICS**

**Structure**

1. *Generations* determine sizes and numbers of surface functional groups, which affects toxicity.
2. *Surface charges* determine cellular interactions and toxicity.
3. *Backbone compositions* determine degradation rates and drug encapsulation potential.
4. *Cores* determine branching degrees and impart potential to add additional functionalities.

**Function**

1. *Targeting ligands* enable selectivity and promote cellular uptake.
2. *Multivalent binding* substantially improves binding avidity by orders of magnitude.
3. *Stimuli-responsiveness* enhances drug delivery through site-specific degradation.
4. *Therapeutic agents* allow killing of target cells.
5. *Imaging agents* enable visual tracking of dendritic nanocarriers *in vitro* and *in vivo*.
6. *PEGylation* reduces nonspecific interactions and increases *in vivo* circulation time.

nanocarriers used for anticancer therapy that have had successful pre-clinical results. Here we will describe some of the most recent progress in dendrimer-based anticancer therapeutics with the aim to provide a set of criteria (summarized in Box 5.1) that should be considered in designing novel dendrimer-based therapeutics.

As noted earlier, coating the surface of dendrimers with a PEG layer is a well-established method used to decrease recognition by the reticuloendothelial system (RES) and to increase the circulation time, thereby enhancing drug delivery efficiencies. Recently, Lim et al. studied a series of PEGylated G2 triazine dendrimers with 12 paclitaxel molecules conjugated through either cleavable ester or ester/disulfide linkages using PC-3 prostate cancer xenografted SCID mice [85]. These dendrimers were well tolerated *in vivo* and could be administered at doses up to 200% of the maximum tolerated dose of free paclitaxel. However, low-level tumor localization and reduced circulation times were observed, suggesting that conjugation of multiple drug molecules may negatively influence the *in vivo* properties of the parent dendrimers. Thus, a key factor in designing dendrimers for drug delivery is to optimize the number of conjugated drug molecules so that important features such as tumor localization and circulating half-life times are minimally deteriorated. To

further enhance the specific delivery of drug molecules from the dendrimer to the tumor site, environmentally sensitive dendrimer-drug linkages have been incorporated. Zhu et al. compared various degrees of PEGylation of PAMAM dendrimers conjugated to doxorubicin (DOX) through acid-sensitive *cis*-aconityl and acid-insensitive amide linkages [77]. Although increasing degrees of PEGylation resulted in a decrease in cytotoxicity, higher PEGylation led to lower cellular uptake of DOX-conjugated dendrimers. At the same PEGylation degree, the acid-labile DOX–dendrimer conjugates were more effective in killing cells than the amide-linked DOX-dendrimers because of the facilitated release of DOX in the lysosomes. *In vivo* evaluation showed that the acid-labile DOX–dendrimers had an improved antitumor activity with an increase in the PEGylation degree because of longer circulation time and more effective tumor accumulation. These results show that the optimally designed conjugation of the drug to a PEGylated dendrimer via a cleavable bond may be beneficial for the treatment of a solid tumor.

One major drawback of dendrimer-based drug delivery systems is their multistep synthesis, which is difficult to scale up. Multifunctional dendrimer-based therapeutics can still be produced with batch-to-batch consistency and specificity toward cancer cells [86]. To improve the processing speed of multifunctional dendrimers, a "one-pot" synthesis method was devised where G5 PAMAM dendrimers were conjugated to predetermined ratios of methotrexate (MTX) and FA. Utilizing this simple approach, similar therapeutic results were obtained to those based on the multistep approach [87]. Although the creation of multifunctional dendrimers is complex, these innovative designs, along with the novel synthetic methodologies, make the dendrimer-based nanocarriers highly promising to reach clinical implementation.

With the rapid advances in genetic analysis using DNA-microarray technologies, the conventional approach to cancer therapy has shifted toward a personalized approach [88]. Gene-expression profiling can now be used to identify prognostic and predictive profiles for each patient, which can give clinicians vital information about which course of treatment would be most advantageous. Furthermore, investigation of cancer-specific surface markers and development of genome-wide association studies provide the tools necessary to bring cancer therapy to a next level by identifying genetic predispositions and their influences on the progression of a disease state [89]. To ultimately succeed in clinical translation, dendrimer-based cancer therapeutics must adapt to utilize the information provided from these biochemical studies.

### 5.4.2 Gene Delivery

The transfer of generic material into a cell to induce, inhibit, or replace gene expression is an additional therapeutic strategy that can be utilized as an effective option for the treatment of multiple diseases. Traditionally, viruses have been used due to their high transfection efficiencies; however, owing to the many safety concerns (potential for mutagenicity, oncogenicity, immunogenicity, and cytotoxicity), a lack of target-specificity, and high-production costs, alternatives that are safe and yet effective are required [90,91]. Cationic nonviral gene delivery vectors that form polyplexes with negatively charged genes are viable options due to their low

cost of preparation, low immunogenicity, and pathogenicity [92]. Unfortunately, the transfection efficiency of nonviral vectors is much lower than that of viruses, and the presence of a large positive charge density often induces nonspecific cytotoxicity. Extensive optimization in nonviral vectors is thus necessary.

PAMAM dendrimers were first reported to mediate the transfection of mammalian cells in culture by Haensler and Szoka [93]. Since then, researchers have designed numerous dendrimers to deliver a wide range of nucleic acids such as antisense oligonucleotides [94], microRNA [95], small interfering RNA [96], and plasmid DNA [97]. In a follow-up study by Szoka, "activated" dendrimers, or dendrimers partially degraded by solvolysis, had a greater than 50-fold enhancement in transfection efficiencies compared to intact dendrimers, which was attributed to an increase in flexibility [98]. Kuo et al. measured the expression of 44,000 genes found in HeLa cells treated with "activated" or intact dendrimers alone or in complex with pDNA [99]. Interestingly, it was found that the differences in molecular architecture induced almost completely different gene-expression profiles. Not surprisingly, surface modification and/or spatial modulation of the positive charges can enhance transfection efficiencies. Kim et al. synthesized G2 PPI dendrimers terminated with arginine. At concentrations as high as 150 μg/ml, a significantly improved transfection efficiency (by fourfold) was obtained over control polyethylenimine (PEI25K), while maintaining 80–90% cell viability [100]. Another group attempted to remove the positive surface charge by synthesizing a PAMAM-like dendrimer with internally quaternized amines and a fully acetylated surface [101]. The modification of the surface and addition of positively charged internal groups drastically reduced the cytotoxicity and enhanced cellular uptake. Surface modification of dendrimers with targeting ligands allows highly effective delivery of genes to their target site. Huang et al. developed a Tf-conjugated PAMAM-PEG dendrimer for brain targeting that showed 2.25-fold higher brain uptake than PAMAM and PAMAM-PEG *in vivo* [102]. Additionally, some groups have designed stimuli responsive dendrimers to increase cellular uptake and transfection efficiency. When short, highly charged oligocations were attached to a PEI-based dendrimeric vector via acid-cleavable linkers, a nearly fivefold increase in transfection efficiency was achieved without increasing cytotoxicity [103]. Rapid progression toward the development of better, more biocompatible, highly effective dendrimer-based gene delivery vectors illuminates the promising impact that dendrimers will have in the future for gene therapy applications.

### 5.4.3 Imaging

The necessity to obtain accurate imaging for *in vitro* and *in vivo* applications has led to the development of many novel nanoparticle-based imaging agents that can be utilized with current micro- and macroscale imaging technologies [104]. The inclusion of imaging agents for nanoparticle tracking and visualization of tumor sites is of great interest to both preclinical researchers and clinicians. In particular, dendrimer-based imaging agents have potential to deliver bioactive compounds and imaging agents simultaneously. Fluorescent imaging agents such as rhodamines,

fluoresceins, and AlexaFluors have been conjugated to dendrimers to allow visualization in cell culture and within tumor sections using fluorescence/confocal microscopy. For *in vivo* imaging, there is a need to develop highly effective and safe contrast agents for imaging that can be used for early detection using MRI. Dendrimers are well suited for the uses as novel MRI contrast agents because of their multivalency, monodisperse characteristics, and relatively large size, compared to low molecular weight gadolinium (Gd) chelates [105]. Several groups have modified the surface of dendrimers with Gd(III) chelates (dendrimer–Gd(III)) and found large proton relaxation enhancements and high relaxivities. For example, PEGylated dendrimers were modified with a tumor-targeting peptide HAIYPRH and modified to chelate Gd(III) [106]. It was found that 98 Gd(III) ions could be loaded per PAMAM dendrimer molecule and that this system could increase the diagnostic efficiency to identify liver cancer. Luo et al. synthesized a set of multifunctional peptide dendritic probes of differing generations that utilized a Gd(III) chelate for imaging and clustered galactose moieties for targeting to liver hepatocytes [107]. The inclusion of targeting ligands with dendrimer-based imaging agents represents a method that can be used to increase image contrast and specificity as opposed to nontargeted molecules. The multifunctionality is a clear advantage of the dendrimers, which allows them to be developed as multifunctional imaging agents that both enhance and expedite the detection and diagnosis of cancers.

## 5.5 DENDRON-BASED HYBRID NANOMATERIALS

It is clear that dendrimers possess many advantageous properties for developing novel therapeutics. Along those lines, each individual dendritic wedge-shaped section, or dendron, that comprises the dendrimer can be used individually or hybridized with other materials to allow creation of a multitude of architectures. Dendrons possess the unique ability to merge the highly desirable properties of dendrimers with the advantages of linear-block copolymers. Unlike the unimolecular structured dendrimers, when engineered with an appropriate hydrophile-lipophile balance (HLB) [108], dendron-based copolymers form self-assembled supramolecular structures. For drug delivery, a variety of dendron-based architectures have been developed and are depicted in Figure 5.5.

Some of the most promising types of dendron-based materials are “bow-tie” hybrid dendrimers [40], linear dendritic block copolymers [16], and dendrimersomes [109]. These materials possess many highly favorable characteristics necessary for drug delivery over comparable dendrimers and linear-block copolymers. First, dendron-based copolymer micelles can overcome the low drug payload disadvantage of dendrimer systems because physical encapsulation into the core is an additional option for the micellar systems. Note that the stability and controllability are the issues in dendrimer encapsulation and the *in vivo* feasibility of the so-called host–guest system is questionable [110]. Encapsulation itself has a significant advantage that there is no need to chemically modify the structure of the drug molecule. Second, the presence of the dendron and its multiple surface functional groups allow

**FIGURE 5.5** A variety of dendron-based architectures for drug delivery. (a) A linear polymer linked to the focal point of a dendron, (b, c) a linear polymer bearing two or multiple dendrons at the end or backbone, (d–f) multiple polymer chains linked to the focal point or the periphery of a dendron. The HLB of dendrons can be engineered by controlling the ratio of hydrophilic to hydrophobic polymers.

multivalent interactions to be integrated. Poon et al. synthesized a micellar drug delivery system consisting of a PEGylated polyester dendron block and a rigid hydrophobic linear polypeptide core-forming block. Multivalent targeting was achieved through incorporation of differing degrees of FA on the dendron surface. These micelles selectively accumulated in xenografted tumors and delivered paclitaxel with a fourfold enhancement and reduced systemic toxicity [17,39]. Third, the dendritic architecture can substantially enhance the thermodynamic stability of self-assembled structures as measured by the CMC. Linear-dendron based copolymers have been reported to self-assemble at extremely low CMCs and at high HLBs. To investigate this phenomenon, we previously synthesized highly PEGylated dendron coils (PDCs) and compared their self-assembly behaviors to linear-block copolymers at similar HLBs [16]. The results showed that PDCs at similar HLBs had CMCs that were 1–2 orders of magnitude lower than those of the linear-block copolymer counterparts. The decrease in CMC is attributable to the preorganized, conical architecture of PDC, which decreases entropic cost during self-assembly [16]. Recently, Percec et al. synthesized 11 polymer libraries consisting of over 100 amphiphilic Janus dendrimers and found that they could self-assemble into highly monodispersed supramolecular structures denoted as “dendrimersomes” [109]. These dendrimersomes combine the mechanical strength of polymersomes and the biological mimicry of liposomes, and their highly branched structures offers the ease of surface functionalization. Even though a vast number of distinct morphologies have been reported in the current literature, the exact parameters that govern the phase-separation behavior and self-assembly of these dendron-based nanomaterials have not been fully understood.

## 5.6 FUTURE PERSPECTIVES

Dendrimers and dendron-based materials are one of the most promising platforms used for drug delivery to date. Extensive *in vitro* and *in vivo* research including those presented in this chapter has illuminated the bright future of dendrimers for drug delivery. Drawbacks of dendrimers, such as limited drug payload and toxicity, can be overcome by engineering the dendrimer structure (e.g., PEGylation), modifying the surface groups (e.g., charge neutralization), and incorporation of functional moieties (e.g., targeting, imaging, therapeutic agents). The choice of dendrimer generation (size) is an additional factor to consider when designing new dendrimer-based drug delivery platforms, because it determines the number of surface functional groups available for conjugation of molecules as well as cellular interactions. However, key challenges, such as limited payload and complex synthetic steps, still remain for dendrimers to be clinically implemented.

Dendron-based nanomaterials have emerged for their potential application in drug delivery. Hybridization of dendrons and linear polymers confers many additional benefits that are not seen in either system alone. This combination of dendritic and linear polymer melds high drug loading potential with multifunctional possibilities and multivalent interactions. However, the dendron systems are relatively new and need to undergo extensive validation processes to prove their potential as effective nanocarriers. Nonetheless, the dendritic structures clearly have significant advantages over the linear polymer counterparts and therefore hold a great promise for various delivery applications. With an optimized design considering the backbone structure, size, surface groups, and multifunctionalities, dendritic nanomaterials will undoubtedly play a key role as a versatile delivery vector in the new era of personalized medicine.

# CHITOSAN-BASED NANOPARTICLES FOR BIOMEDICAL APPLICATIONS

Heebeom Koo, Kuiwon Choi, Ick Chan Kwon, and Kwangmeyung Kim

*Center for Theragnosis, Biomedical Research Institute, Korea Institute of Science and Technology, Seongbuk-gu, Seoul, Republic of Korea*

## 6.1 CHITOSAN AS A BIOPOLYMER

In recent years, progress in the field of biotechnology and nanotechnology has made a huge impact on biomedical fields. In addition to the improvement in mechanical devices, nanoparticles have emerged as a multifunctional platform for both diagnosis and therapy of various diseases [1,2]. Researchers have developed various kinds of nanoparticles using polymers, lipids, iron, gold, silica, and so on [3,4]. Among them, polymers are the most widely used components in fabricating nanoparticles [5]. Their major advantage is that their physical or chemical properties can be easily controlled by changing the molecular weights or chemical structures [6]. Therefore, a number of polymer-based nanoparticles have been developed and applied to biomedical fields [7].

Chitosan is one of the representative natural polymers, which is derived from chitin and frequently used for the development of nanoparticles [8,9]. Chitin is the main component of crustacean shell and is composed of β-(1,4)-2-acetamido-D-glucose linked via (1–4) glycosidic bonds. Chitosan is produced by deacetylation of chitin, and the number of amine groups is dependent on the degree of deacetylation. These amine groups endow many useful characteristics with chitosan.

Water solubility of chitosan is mainly dependent on the protonation of amine groups. Because the $pK_a$ value of this amine group is about 6.5, chitosan is generally

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*,
Edited by Shayne C. Gad

soluble in solvents with pH below 6.5 but insoluble in solvents with neutral or basic pH [10]. Even though low-molecular-weight chitosans below ~50 kDa are soluble at neutral pH, most chitosans originally have relatively low solubility in water, which is a major hurdle for further development. To enhance the water solubility of chitosan, various chitosan derivatives have been developed by chemical modification. One way to enhance water solubility is to introduce additional cationic or anionic charged groups. Quaternized chitosan (trimethyl chitosan), sulfated chitosan, and carboxymethyl chitosan are representative chitosan derivatives which have charges at a neutral condition [11–13]. Alternatively, conjugation with highly water soluble poly(ethylene glycol) (PEG) or glycol groups (one unit of ethylene oxide) can enhance the solubility of chitosan without additional charges [14–16].

Chitosan is distinguished from many biopolymers by its amine groups providing useful information on its properties. First, this amine group can bind to anionic surface of cellular membrane, enabling efficient cellular adhesion and uptake [17]. This property is very useful in biomedical applications such as drug or gene delivery. Second, chitosan can also bind to anionic DNA or RNA by electronic interactions with these amine groups [18,19]. Consequently, chitosan is a very attractive material for developing gene carriers [20]. Finally, many other molecules can be conjugated to chitosan via these amine groups [21]. This point is particularly important because amide coupling of amine and carboxylic acid groups is the most widely used conjugation method. In addition, a number of functional molecules such as fluorescence dyes are commercially available as activated with *N*-hydroxysuccinimide ester (NHS) for conjugation to these amine groups [22].

Biodegradability and biocompatibility of chitosan facilitate its use for biomedical applications. The oral $LD_{50}$ value of chitosan is more than 16 g/kg in mice, which is very high and demonstrates the biocompatibility of chitosan [23]. It can be degraded to low-molecular-weight molecules by various enzymes secreted from the kidney. Owing to this biocompatibility, its use as a wound dressing agent was approved for human use by the U.S. Food and Drug Administration (FDA) [24]. On the basis of these points, chitosan is generally believed as a biocompatible biopolymer by many researchers. However, modified chitosans may show more delayed renal excretion due to limited interactions with enzymes [25].

In this review, we focus on chitosan-based nanoparticles for imaging and drug/gene delivery. We introduce many studies on chitosan nanoparticles, which evaluated biological effects in living systems such as cultured cells or animal models. Furthermore, we describe important considerations in developing chitosan-based nanoparticles for diagnosis and therapy of diseases.

## 6.2 CHITOSAN NANOPARTICLES FOR IMAGING

### 6.2.1 Optical Imaging

Optical imaging is generally based on fluorescence or luminescence. The advantages are easy handling, high sensitivity, and relatively low cost of imaging equipment [26]. Optical imaging nanoprobes can be prepared by simple conjugation or loading

of commercial fluorescence dyes to nanoparticles [27]. Nanoparticles with targeting ability can be used for optical imaging of a specific disease through long-term blood circulation and high accumulation in the target site. For *in vivo* optical imaging, the near-infrared (NIR) region of fluorescence (about 650–900 nm) is frequently used due to the relatively low interference by hemoglobin and water [28].

Ranjan et al. showed that chitosan-based polymeric nanoparticles can be used in *in vivo* optical imaging by simple loading of indocyanine green (ICG), an FDA-approved commercial fluorescence dye [29]. They developed nanoparticles with poly(L-lactide-*co*-epsilon-caprolactone) and poloxamer, and ICG was encapsulated in the nanoparticles. The surface of nanoparticles was further modified by chitosan. The positive charge of chitosan enhanced cellular uptake and tissue accumulation during both *in vitro* and *in vivo* experiments. These results were obtained by NIR optical imaging of the loaded ICG.

Recently, Kim's group demonstrated an excellent tumor-targeting ability of their glycol chitosan nanoparticles by optical imaging [30]. Glycol chitosan is a chitosan derivative with good water solubility. Glycol groups also provide cationic amine groups with PEG-like shielding effects inhibiting interactions of nanoparticles with anionic serum protein. Glycol chitosan nanoparticles were synthesized by conjugating hydrophobic 5β-cholanic acids to hydrophilic glycol chitosan [31] (Figure 6.1a, b ). The average size of glycol chitosan nanoparticles was about 250 nm, and NIR fluorescence dye Cy 5.5 was conjugated to it for optical imaging. Owing to the small size, deformability, fast uptake into tumor cells, and the shielding effect of glycol groups, glycol chitosan nanoparticles could be efficiently accumulated within tumors via the enhanced permeability and retention (EPR) effect in newly generated tumor vessels [32–34]. The tumor-targeting ability of glycol chitosan nanoparticles was analyzed in various tumor models. In a flank tumor model, it showed long-term circulation and high accumulation in tumor tissues for a prolonged period (Figure 6.1c). In particular, the EPR effect in tumor tissues and fast penetration of nanoparticles were monitored with live optical imaging [35] (Figure 6.1d). Subsequently, a significant correlation between angiogenesis in tumors and *in vivo* behavior of glycol chitosan nanoparticles was shown in a brain tumor model in a time-dependent manner (Figure 6.1e). In a liver tumor model, the high fluorescence signals in tumor tissues than in surrounding normal liver tissues demonstrated the ability of glycol chitosan nanoparticles to escape from the reticuloendothelial system (RES) of the liver (Figure 6.1f). Finally, specific detection of metastatic tumors with them was shown in a lung metastasis tumor model (Figure 6.1g). Furthermore, successful optical imaging of unintended secondary metastatic tumors on forefoot showed the potential of the early detection of metastasis in patients. These results demonstrate the utility of fluorescently labeled chitosan nanoparticles in optical imaging of various cancers.

### 6.2.2 Magnetic Resonance (MR) Imaging

Nowadays, magnetic resonance (MR) imaging is indispensable for the diagnosis of many diseases in clinical settings. MR imaging mainly provides anatomical imaging

**FIGURE 6.1** Chitosan nanoparticles for optical imaging. (a) Chemical structure of Cy5.5 and 5β-cholanic acid conjugated glycol chitosan. (b) Schematic illustration of a self-assembled glycol chitosan nanoparticle. (c) *In vivo* and *ex vivo* tumor imaging with chitosan nanoparticles in left flank tumor model. (d) Vascular penetration imaging in left flank tumor tissue with chitosan nanoparticles. (e) Brain tumor imaging with chitosan nanoparticles. (f) Liver tumor imaging with chitosan nanoparticles (white arrows marks the margin between normal and tumor tissue.). (g) Lung and secondary metastatic tumor imaging with chitosan nanoparticles. (*Source*: Figures reproduced with permission from Reference [30].)

of organs and tissues, and can visualize internal disorders of the body resulting from diseases. MR imaging is generally categorized into two modes: longitudinal (T1) mode and transverse (T2) mode [36].

In T1 MR imaging, gadolinium (Gd)-based contrast agents can reduce T1 relaxation time by interacting with water and provide bright signals. Gd ions are generally entrapped by chelators such as tetraazacyclododecane tetraacetic acid (DOTA) or diethylenetriaminepentaacetic acid (DTPA) for MR imaging [37]. These chelators can be chemically conjugated to functional nanoparticles for improvement of T1 contrast imaging of target tissues [38]. Since Gd-based T1 MR imaging is based on interactions with water molecules, Gd chelators should be present on the outer environment rather than inside of the nanoparticles. Recently, Kim's group

developed a dual imaging probe by conjugation of Gd-DOTA and Cy 5.5 to glycol chitosan backbone of the nanoparticles [39]. In addition to optical imaging by Cy 5.5, intense T1 MR signal of the resulting nanoparticles revealed bright tumor tissues in MR images of tumor-bearing mice.

On the other hand, T2 MR imaging agents, such as iron oxide nanoparticles, shorten the transverse relaxation time and provide dark images of target tissues [40]. Iron oxide nanoparticles are generally synthesized at a high temperature using fatty acids as a surfactant. The iron oxide nanoparticles with such a hydrophobic surface should be hydrophilically modified for applications in aqueous environment of the body [41]. Consequently, many researchers conjugated hydrophilic polymers to them or encapsulated them in hydrophilic nanoparticles to increase water solubility. Chitosan can be employed for varying purposes. For example, Lee et al. developed iron oxide-loaded chitosan nanoparticles with hydrophobic linoleic acid-conjugated water-soluble chitosan and hydrophobic fatty acid-coated iron oxide nanoparticles [42]. These chitosan nanoparticles were stable in an aqueous condition for a long time and generated dark T2 signals in hepatocytes in mice after intravenous injection. The same group also synthesized chitosan nanoparticles conjugated with oleic acid for self-assembly and Cy 5.5 dyes for optical imaging [43] (Figure 6.2a). Subsequently, oleic acid-coated iron oxide nanoparticles were encapsulated in these chitosan nanoparticles for T2 MR imaging (Figure 6.2b). The resulting nanoparticles could provide both optical imaging and T2 MR signals (Figure 6.2c, d). In a U87MG brain-tumor-bearing mouse model, the tumor site was marked by optical fluorescence imaging and T2 MR imaging simultaneously (Figure 6.2e–g).

### 6.2.3 Computed Tomography (CT) Imaging

Computed tomography (CT) is a powerful imaging technique, which can provide two- or three-dimensional images of living subjects. CT can provide anatomical images of bones and tissues with very high spatial resolution. For enhanced CT imaging, iodine-based contrast agents are used in clinical settings [44]. However, owing to the renal toxicity and high viscosity of iodine solutions, there is an urgent need for alternative CT imaging agents. Recently, many researchers have focused on gold nanoparticles as a new CT imaging agent because gold nanoparticles present a high X-ray absorption coefficient for intense CT signals [45]. Consequently, several groups have tried targeted delivery of gold nanoparticles for *in vivo* CT imaging [46].

Recently, Sun et al. developed a gold nanoparticle-based optical/CT dual imaging probe with glycol chitosan for *in vivo* tumor diagnosis [47]. They used glycol chitosan as a reducing and stabilizing agent during fabrication of gold nanoparticles. Glycol chitosan polymers tightly adsorbed onto the surface of a gold nanoparticle via primary amine groups as reducing agents. Then, matrix metalloproteinase (MMP) activatable peptide probes were conjugated to the glycol chitosan-coated gold nanoparticles for optical imaging [48] (Figure 6.3a). This glycol chitosan-coated gold nanoprobe showed a long circulation time and high accumulation in tumor sites for diagnosis. In a tumor-bearing mouse model, optical and CT imaging of tumor

**FIGURE 6.2** Chitosan nanoparticles for optical/MR imaging. tissues was successfully obtained with this nanoprobe (Figure 6.3b, c). Importantly, this research is a good example of a multimodal imaging nanoprobe with synergetic effects [49]. CT imaging can provide three-dimensional anatomical imaging of tumor tissues in the body, while highly sensitive optical imaging can provide

**FIGURE 6.3** Chitosan nanoparticles for optical/CT imaging. (a) Schematic illustration of an MMP-specific glycol chitosan-coated gold nanoparticle and their MMP triggered fluorescence activation. (*Source*: Figures reproduced with permission from Reference [47].)

precise biological information of MMP enzymes in tumor tissues. Benefits of combination should be further explored in the development of multimodal imaging nanoprobes [40].

### 6.2.4 Positron Emission Tomography (PET) Imaging

Positron emission tomography (PET) images are obtained by tracking positron emitting radioisotopes such as $^{11}C$, $^{18}F$, $^{64}Cu$, and $^{68}Ga$ in living systems. A principal advantage of PET is that it is the most widely used functional imaging technique in current clinical settings. Molecularly targeted radioisotopes and high sensitivity of PET can provide biological information of the disease [50]. Moreover, PET imaging enables quantitative analysis of the pharmacokinetics and pharmacodynamics of injected molecules with radiolabeling [51]. $^{18}F$-fluorodeoxyglucose ($^{18}F$-FDG) is the most commonly used and commercialized imaging agent for PET, and many other agents are currently developed.

Yang et al. synthesized $^{18}F$-labeled galactosylated chitosan for hepatocyte imaging with PET [52]. The galactosyl group can bind to hepatocytes in the liver via asialoglycoprotein receptors [53]. The galactosylated chitosan was synthesized by coupling the carboxylic acid group of lactobionic acid and the amine group of chitosan. The resulting chitosan conjugate was labeled with $^{18}F$ by *N*-succinimidyl-4-$^{18}F$-fluorobenzoate. They showed high accumulation in liver tissue after intravenous injection. Injection of excess neogalactosylalbumin as competitive molecules for receptors prevented accumulation of the galactosylated chitosan nanoparticles.

Recently, Tsao et al. reported that $^{68}Ga$-glycopeptide composed of glutamate peptide and chitosan could be applied for PET imaging of tumor angiogenesis [54]. $^{68}Ga$ is one of the most attractive radioisotopes that can be produced from generators for PET imaging [55]. This glycopeptide could efficiently enter tumor cells via glutamate transporters. Tumor tissues in New Zealand rabbits were observed in PET images with $^{68}Ga$-glycopeptide, and their accumulation was higher than that of commercial $^{18}F$-FDG. In addition to these papers, a large number of chitosan nanoparticles showing superior target specificity have been developed for PET imaging [9,56].

### 6.2.5 Ultrasound (US) Imaging

The basic mechanism of ultrasound (US) imaging is the analysis of acoustic signals resulting from reflection or scattering of applied ultrasonic waves inside the body [57]. US imaging has many advantages such as relatively low capital costs, simplicity of the procedure, direct imaging without delay, and low cost of imaging. [58] For the enhancement of US contrast, gas-encapsulated nano- or microbubbles are generally used during imaging [59]. As the core materials of these bubbles, air or inert perfluorocarbon gas has been used. These gas cores are encapsulated by shell materials such as lipids or polymers to enhance the stability and water solubility of bubbles for intravenous injection to patients. Albumin-coated Albunex® and lipid-coated Sonovue® are the most widely used US contrast agents at present.

Liu et al. used chitosan as coating materials of perfluorocarbon gas in developing as an US contrast agent [60]. They synthesized a core-shell structure with silica and chitosan and made hollow nanoparticles by cross-linking of chitosan shell with glutaraldehyde and removing silica cores in hydrofluoride solution. Subsequently, liquid-form perfluoropentane was loaded into the core of nanoparticles. The resulting chitosan/perfluoropentane nanobubbles generated intense US signals in PBS solution similar to Sonovue. Although only a few US contrast agents have been developed with chitosan nanoparticles so far, many chitosan derivatives may be useful for the fabrication of microbubbles for *in vivo* US imaging due to their biocompatibility and wide availability.

## 6.3 CHITOSAN NANOPARTICLES FOR THERAPY

### 6.3.1 Drug Delivery

Owing to the positive charge of chitosan, some chitosan nanoparticles have been developed based on electronic interactions with anionic polymers. Sung's group developed pH-responsive nanoparticles with cationic chitosan and anionic poly-γ-glutamic acid [61]. The ionic cross-linking in this particle was further enhanced with tripolyphosphate (TPP) and magnesium sulfate [62] (Figure 6.4a). From pH 2.5 to 6.6, the nanoparticle is relatively stable because both chitosan and poly-γ-glutamic acid are ionized. However, chitosan is deprotonated at pH above 7.0, and nanoparticles become unstable and can release drugs. This study showed that pH-responsive protonation of chitosan can be applied for controlling drug release.

Many previous papers proved that the amine and carboxylic acid groups of chitosan could bind to glycoproteins in mucus by hydrogen bonding [63]. Moreover, recent studies showed that the tight junctions in monolayers of enterocytes could be opened after binding with chitosan molecules [64,65]. Consequently, these properties make chitosan nanoparticles promising drug carriers for oral drug delivery [66,67]. Sung group applied their pH-responsive chitosan nanoparticles to oral delivery of insulin [68,69]. They showed superior transport of insulin across Caco-2 cell monolayers by chitosan nanoparticles using confocal microscopy (Figure 6.4b). The efficient insulin delivery to the duodenum and jejunum by these particles has also been successfully proved in rat models. Furthermore, the time-dependent blood glucose level data in a diabetic rat model demonstrated the great potential of the chitosan nanoparticles as a protein drug carrier for oral delivery.

Because of its cationic charge, chitosan can bind to anionic drugs directly. Heparin is a highly sulfated glycosaminoglycan with intense anionic charge. It is clinically used as a potent anticoagulant, which can form an inhibitory complex with anitithrombin [70]. Sung's group showed that cationic chitosan can bind to anionic heparin and form self-assembled nanoparticles [70]. The chitosan–heparin nanoparticles were successfully applied to the oral delivery of heparin. Chitosan enhanced the absorption of heparin in the gastrointestinal tract, resulting in effective anticoagulation after oral administration in a rat model.

**FIGURE 6.4** Chitosan nanoparticles for drug delivery. (a) Schematic illustration of multi-ion-cross-linked chitosan nanoparticles with poly-γ-glutamic acid (γ-PGA). (b) Fluorescence images of Caco-2 cell monolayers with chitosan nanoparticles. (*Source*: Figures reproduced with permission from Reference [61].)

In case of hydrophobic drugs, amphiphilic chitosan nanoparticles may be a good carrier candidate [71]. Zhao et al. synthesized chitosan nanoparticles by conjugation of hydrophobic linoleic acid and hydrophilic poly(β-maleic acid) to chitosan backbone [72]. Poly(β-maleic acid) could improve the water solubility of original chitosan and facilitate self-assembly of the chitosan conjugate in nanoparticles. A hydrophobic anticancer drug, paclitaxel, was stably loaded into this chitosan nanoparticle, and its therapeutic efficacy has been proved in a tumor-bearing mouse model. Recently, Lee et al. synthesized *N*-acetyl histidine conjugated glycol chitosan

nanoparticles and showed successful therapeutic results following an intravenous injection of doxorubicin-loaded nanoparticles in tumor-bearing mice [73]. The biodistribution of nanoparticles and doxorubicin was monitored by optical and radioisotope imaging. In particular, they showed that the ratio of hydrophobic moiety in nanoparticles affected the amount of doxorubicin accumulated in tumor tissues. This study shows that the optimization of nanoparticles for efficient drug delivery is important, and that real-time *in vivo* imaging technique can be a useful tool for optimization [74].

### 6.3.2 Gene Delivery

Chitosan has long been considered a highly attractive material for developing gene carriers due to its primary amine groups and cationic charges. Chitosan can form a stable complex with nucleotides and increase their cellular uptake. A number of gene delivery carriers were developed with original or modified forms of chitosan, and these efforts are summarized in recent reviews [18,75]. We introduce some representative examples in this section.

Chitosan can be used as a gene carrier in its original form. Leong and colleagues reported that the Factor VIII DNA polyplexes with chitosan could be used in oral gene delivery [76]. Molecular weight and the degree of deacetylation of chitosan have a significant influence on transfection efficiency. In this study, they used chitosan with a molecular weight of 390 kDa and a degree of deacetylation of 84%. Owing to the mucoadhesive character of chitosan, the transfection efficiency with chitosan by oral delivery was more enhanced compared with naked DNA. Moreover, the increased thrombin generation and phenotypic correction in hemophilia A mouse models proved that chitosan was an attractive gene carrier for oral delivery.

Many researchers who are interested in gene therapy of lung diseases have tried several administration routes, including pulmonary administration. Mohri et al. introduced spray–freeze–dried powder of chitosan and DNA for inhalation [77]. They achieved high recovery of dried genes through this method and showed that an optimized amount of chitosan could enhance gene transfection. With dual imaging based on fluorescence and luminescence, the pulmonary administration and gene expression were evaluated in a mouse model. The intense luminescence signal in lung tissues showed that chitosan powder produced with spray–freeze–dried method could be used as pulmonary gene carriers.

To enhance the target cell specificity for gene delivery, some receptor-binding moieties have been conjugated to chitosan nanoparticles [78]. Zheng et al. used folate as a targeting moiety, which can bind to folate receptors abundant in various tumor cells [79]. They synthesized folate conjugated *N*-trimethyl chitosan with high water solubility and DNA condensing ability [80]. The resulting polymer showed high transfection efficiency *in vitro*, and its cytotoxicity was lower than that of synthetic polymers such as polyethylenimine. For hepatocyte targeting, galactosylated chitosan-polyethylenimine (PEI) was synthesized by Jiang and colleagues [81]. It enhanced the transfection efficiency in liver cells by binding to asialoglycoprotein receptors.

In recent years, small interfering RNA (siRNA) is emerging as a promising therapeutic modality, which can specifically suppress the expression of target protein with no adverse effects [82,83]. Oh group developed poly-L-arginine derivatives of chitosan (CS–PLR), where PEG was also conjugated to inhibit their aggregation under aqueous conditions [84] (Figure 6.5a). This chitosan nanoparticle can form a stable complex with siRNA, and its gene silencing effect was confirmed under cell culture conditions with green fluorescence protein. This PEG–CS–PLR showed enhanced gene silencing efficiency and cellular uptake *in vitro* compared to Lipofectamine™ 2000, commercialized transfection agent and non-PEGylated CS–PLR (Figure 6.5b, c). Finally, they made a tumor-bearing mouse model with B16F10 tumor cells expressing red fluorescence protein (RFP). After intratumoral injection of chitosan nanoparticles containing RFP sequence siRNA, the red fluorescence in tumor site was reduced, proving the *in vivo* gene silencing effect (Figure 6.5d).

Howard and colleagues showed therapeutic results of chitosan/siRNA nanoparticles by intraperitoneal injection [85]. They used an unmodified chitosan with a molecular weight of 114 kDa and a deacetylation degree of 84%. At pH 5.5, chitosan nanoparticles were formed with siRNA of tumor necrosis factor-α (TNF-α)

**FIGURE 6.5** Chitosan nanoparticles for gene delivery. (a) Chemical structure of PEG–polyarginine–chitosan (PEG–CS–PLR). (b) *In vitro* silencing of green fluorescence protein (GFP) expression with chitosan nanoparticles. (c) Cellular uptake analysis using fluorescently labeled siRNA. *denotes significant difference from other groups ($p < 0.05$) (d) *In vivo* silencing of red fluorescence protein (RFP) expression with chitosan nanoparticles (white circles denote tumor site). (*Source*: Figures reproduced with permission from Reference [84].)

sequence. During *in vitro* transfection in murine peritoneal macrophages, the chitosan nanoparticles showed efficient knockdown of TNF-α gene. Then, a collagen type II-induced arthritis (CIA) mouse model was established by immunization with an arthrogen-CIA collagen emulsion. After intraperitoneal injection of chitosan nanoparticles, significant anti-inflammatory effect was observed in the CIA model.

For intravenous injection, chitosan nanoparticles containing genes should provide long-term circulation and resist aggregation in blood. Huh et al. reported that glycol chitosan/PEI nanoparticles could be applied to tumor-targeted siRNA delivery via intravenous injection [86]. They made glycol chitosan/PEI nanoparticles by conjugation with 5β-cholanic acid to each polymer. The resulting mixture with two polymer conjugates were self-assembled into a nanoparticle form in an aqueous condition prior to siRNA addition. PEI enhanced the electronic interactions with siRNA, and the glycol group of glycol chitosan enhanced water solubility and inhibited aggregation with serum proteins [87]. In tumor-bearing mice models, this nanoparticle formulation showed approximately fivefold higher accumulation of siRNA compared to the free form of siRNA. *In vivo* gene silencing was also demonstrated in an RFP/B16F10 tumor-bearing mouse model. These results demonstrate the huge potential of chitosan nanoparticles for clinical application as gene carriers.

### 6.3.3 Photodynamic Therapy

Photodynamic therapy is one of the therapeutic modalities in clinical fields, mainly used in treatments of cancers or skin diseases [88]. It employs photosensitizers, which can generate cytotoxic singlet oxygen when irradiated at an appropriate wavelength. Consequently, targeted delivery of these photosensitizers can result in cell death or tissue destruction in disease site for therapeutic purpose [89]. If they are not delivered to target disease site properly, the therapeutic efficacy reduces and they can result in unintended phototoxicity in normal tissues. Therefore, efficient delivery systems of photosensitizers are needed for successful photodynamic therapy [90].

In 2010, Kim's group applied the amphiphilic glycol chitosan nanoparticles for tumor-targeted delivery of a hydrophobic photosensitizer, protophorphyrin IX (PpIX) [91]. The nanoparticles achieved faster cellular uptake of PpIX than free PpIX, and this uptake rate reflected the efficient death of tumor cells. The *in vivo* data showed high accumulation of PpIX in tumor site during optical imaging and successful tumor suppression in a SCC7 tumor-bearing mouse model upon laser irradiation.

One of the attractive features of photosensitizers is the simultaneous generation of fluorescence with singlet oxygen upon irradiation [92]. This intrinsic fluorescence can provide easy tracking of the photosensitizers in both cell and animal models [93,94]. Kim's group also reported that this fluorescence can be applied to the time-dependent tracking of photosensitizers in a tumor-bearing mouse model by optical imaging [95]. They synthesized two types of glycol chitosan nanoparticles based on physical loading and chemical conjugation of photosensitizers, and imaged biodistribution of the photosensitizers noninvasively by NIR fluorescence (Figure 6.6a).

**FIGURE 6.6** Chitosan nanoparticles for photodynamic therapy. (a) Schematic illustration of two kinds of glycol chitosan nanoparticles containing photosensitizer, chlorin e6 (Ce6). (b) *In vivo* biodistribution of photosensitizers delivered by chitosan nanoparticles. (c) *In vivo* photodynamic therapy with chitosan nanoparticles. (*Source*: Figures reproduced with permission from Reference [95].)

The results showed that the loss of photosensitizers by unintended burst release was significantly large in case of physical loading (Figure 6.6b). This loss of photosensitizers could result in lower therapeutic efficacy when compared to photosensitizer-conjugated nanoparticles (Figure 6.6c). This problem of burst release during blood circulation should be overcome by innovative methods to obtain improved therapeutic results [96].

## 6.4 PROMISES, LIMITATIONS, AND FUTURE PERSPECTIVES OF CHITOSAN NANOPARTICLES

Until now, various forms of nanoparticles have been developed based on chitosan for biomedical applications including imaging, drug delivery, and gene delivery [97]. Chitosan is a biodegradable and biocompatible natural polymer with primary amine groups and cationic charges, and many researchers have explored chitosan due to its unique properties. Consequently, valuable results have been obtained with chitosan nanoparticles in cell and animal models. However, some hurdles remain to be overcome for their clinical applications.

The first challenge is the approval from the Food and Drug Administration (FDA) [98]. For commercialization of chitosan nanoparticles for clinical applications, only an FDA-approved form of chitosan should be used. Various types of modifications or

conjugations are performed to improve the functionality of chitosan [99]. However, additional synthetic modification steps are likely to delay the commercialization and clinical translation of nanoparticles.

The second challenge is the quality control of chitosan nanoparticles during manufacture. Physicochemical properties such as size, potential, and molecular weight of chitosan nanoparticles are not as uniform as those of single molecular drugs or imaging agents. This heterogeneity may not be a significant issue at an experimental level, but it may become a potential obstacle from a commercial standpoint. In fact, quality control is a common challenge for most nanoparticle systems for biomedical applications.

While chitosan nanoparticles have a long way to go, there are a number of exciting ongoing studies that employ chitosan in developing nanoparticles for biomedical applications [100]. Investigations are warranted with regard to the potential of chitosan nanoparticles as a system to improve the quality of clinical treatments in the foreseeable future.

## 7.1 INTRODUCTION

Polymeric nanomedicine, an emerging field that involves the use of drug-containing polymeric nanoparticles (NPs) for cancer treatment, is expected to alter the landscape of oncology [1]. The medical application of nanotechnology has been extensive: roughly 40 nanomedicines have already been approved by the Food and Drug Administration (FDA) for clinical use [2–4] and a handful of NPs are currently in preclinical investigations [2,5]. Incorporation of chemotherapeutic agents in NP delivery vehicles can improve water solubility, reduce clearance, reduce drug resistance, and enhance therapeutic effectiveness [6]. Broadly speaking, two approaches have been used to load drugs in NPs for delivery. One is to encapsulate drugs within NPs via noncovalent bonds, that is, distribution of the drug throughout a polymeric matrix during formulation (Figure 7.1a) [7]. The second loading strategy is the formulation of NPs using polymer–drug conjugates, a technique first proposed in 1975 (Figure 7.1b) [8]. In this chapter, we discuss the pros and cons of the two strategies and introduce newly developed polymer-drug conjugates—so-called nanoconjugates—as a formulation strategy which addresses challenges faced by both encapsulates and conjugates

**FIGURE 7.1** Pros (black) and cons (gray) of (a) nanoencapsulates (NEs) and (b) polymer–drug conjugates. We propose (c) nanoconjugates (NCs) with reduced heterogeneity to address the challenges in both encapsulated and conjugated systems.

(Figure 7.1c). Along the way, we also discuss topics related to regioselective polymer–drug conjugation chemistry, *in vitro* formulation and characterization, and present preliminary *in vivo* studies that highlight the potential clinical translation of nanoconjugates.

## 7.2 CURRENT STATUS OF NANOENCAPSULATES AND POLYMER–DRUG CONJUGATES

### 7.2.1 Nanoencapsulates

Nanoparticles loaded with a drug via encapsulation within a polymer matrix are termed nanoencapsulates. Although nanoencapsulate formulation is straightforward in both concept and fabrication, their clinical use is challenged by a variety of issues (Figure 7.1a). First, nanoencapsulates often show "burst" drug release profiles in aqueous solution, with as much as 80–90% of the encapsulated drug released during the first few to tens of hours [9]. The rapid drug release, also called dose dumping, can prevent the drug from operating within its therapeutic window and cause severe systemic toxicity [10]. Second, drug loading in nanoencapsulates is very low—typically in the range of 1–5% for most NPs studied—and is widely variable depending on the amount of drug being used, the hydrophobicity/hydrophilicity of the drug as well as the compatibility between the drug and the polymer [9,11]. Drug loading, in particular, is a critical measure of the feasibility of nanoencapsulate delivery systems in clinical

settings [11]. At low drug loading, large amounts of delivery vehicles are needed to achieve therapeutic concentrations. However, because of the limited body weight and blood volume of animals, administration volumes are fixed. For mice with 20–30 g body weight, the intravenously injected volume must be kept around 100–200 μL [12]. Thus, the intravenous administration of NPs with 1% drug loading in a 100 μL solution at a dose of 50 mg/kg (e.g., docetaxel) would require a 1 g/mL NP solution. In practice, it is impossible to formulate such concentrated solutions and inject them intravenously. Another problem related to drug loading is the lack of a general strategy to achieve quantitative drug encapsulation in many NPs (e.g., polylactide (PLA) and poly(lactic-*co*-glycolic acid) (PLGA) NPs). In this instance, nonencapsulated drugs may self-aggregate, thus complicating their removal from the NPs [13]. Ultimately, these formulation challenges significantly impact the processability and the clinical translation of nanoencapsulate delivery vehicles for cancer therapy.

### 7.2.2 Polymer–Drug Conjugates

As difficulties facing nanoencapsulate drug loading began emerging, considerable interest was shifted to drug delivery strategies employing polymer–drug conjugates (Figure 7.1b). In fact, a polymer–protein drug conjugate has already been approved for use in Japan, and a handful of other polymer–drug conjugates are presently transitioning from later clinical trials to the wider market [10,14]. One of the first systems explored, *N*-(2-hydroxylproply)methacrylamine (HPMA) polymer–drug conjugates developed by Duncan and Kopecek in the late 1970s, has led to various clinical trial candidates [14,15]. Other interesting types of polymer–drug conjugates include cyclodextrin-containing polymers with conjugated camptothecin developed by Davis laboratory (IT-101) [16–20] and dendritic polyester–drug conjugates developed by Frechet and coworkers [21,22].

One of the primary challenges facing polymer–drug conjugate delivery systems is the actual conjugation step. Not only does the conjugation often require extensive post-conjugation purification steps, the heterogeneity of polymer–drug conjugates arising from nonsite-specific coupling reactions may also present bottlenecks to the clinical translation [10]. As shown in Figure 7.2, heterogeneities of polymer–drug conjugates result from (1) molecular weight distributions (MWDs, Mw/Mn) of the polymers (Figure 7.2a), (2) lack of control of the drug conjugation site on the polymer backbone (Figure 7.2b), and (3) lack of regioselectivity with regard to the conjugation site on drugs with multiple conjugation-amenable functional groups (Figure 7.2c). This last point is particularly relevant, as many of the best-selling anticancer small molecule drugs (e.g., paclitaxel, docetaxel, and doxorubicin) contain multiple functional groups (e.g., multihydroxyl groups in all three agents; ketone and amine groups in doxorubicin) for conjugation [23]. In the past several decades, there have been numerous efforts to minimize heterogeneities within polymer–drug conjugates. These include the development of polymers with low MWDs (e.g., dendrimers) [22,24–31], the conjugation of therapeutic agents to specific sites along the polymer backbone (e.g., the termini) [16,32–38], and the activation of specific functional groups on the therapeutic agents by means of

**FIGURE 7.2** Heterogeneities in polymer-drug conjugates: (a) polymer–drug conjugates with a broad distribution of polymer chain lengths; (b) polymer–drug conjugates in which the conjugation site on the polymer backbone is uncontrolled; (c) polymer–drug conjugates in which a multifunctional therapeutic agent is conjugated without regioselectivity. Our solution to the heterogeneity problem: (d) drug-initiated, controlled polymerization for the synthesis of polymer–drug conjugates with low MWDs; the drug molecules are conjugated regioselectively to the polymer termini.

protection/deprotection chemistry [39,40]. However, concise synthetic strategies that yield polymer–drug conjugates with minimal heterogeneity for clinical application are still lacking (Figure 7.2a–c).

## 7.3 NANOCONJUGATES: DESIGN AND SYNTHESIS

### 7.3.1 Design and General Consideration

We present here a new synthetic strategy to address challenges faced by both nanoencapsulates and polymer–drug conjugates. In particular, we focus on chemistry that allows for site-specific conjugation of a drug to a polymer with a narrow molecular weight distribution (MWD) with quantitative incorporation efficiency.

In designing such a synthetic strategy, we first considered chemical systems which already benefit from controlled and precise chemistry, like the well-established and controlled polymerization methodologies allowing for the preparation of polyesters [41,42], polypeptides [43,44], and hydrocarbon-based synthetic biopolymers [45] with precisely controlled molecular weights (MWs) and narrow MWD. By incorporating these existing strategies in our design, polymer–drug conjugates can be produced with precise and homogeneous chemical structure and, ultimately, improved performance.

Ring-opening polymerization (ROP) for the preparation of PLA polyesters has been investigated extensively [46,47]. The polymerization reaction typically involves lactide (LA) ring opening by a metal–alkoxide ($L_nM$–OR) to form a RO-terminated LA–metal alkoxide ($ROOCCH(CH_3)O\text{-}ML_n$) followed by chain propagation to form RO-terminated PLA [41,46,47]. According to this mechanism, the RO group ultimately is connected to the PLA terminus through an ester bond (Figure 7.3a). This process is well understood and has been used extensively for the

**FIGURE 7.3** (a) Mechanism of ROP of PLA initiated by R-OH/BDI-metal catalyst. We propose the mechanism can be applied to (b) complex molecules with dense hydroxyl groups, for example, Ptxl, to initiate ROP. (c) Regioselective coordination of (BDI-II)$ZnN(TMS)_2$ onto 2′-OH of Ptxl to initiate ROP of LA. The polymers can be nanoprecipitated with PLGA–mPEG or PLA–mPEG to formulate sub-120 nm NPs.

incorporation of hydroxyl-containing small molecules [38], macromolecules [48], and NPs [49] to the termini of PLA.

In the context of delivery technology, hydroxyl groups of drugs can be utilized to achieve controlled living polymerization of LA. The hydroxyl group is the most abundant functional group in natural products, being found in about 65% of the ~78,000 known pharmacophores as well as in several of the best-selling anticancer small molecule drugs. Thus, the active initiator for PLA polymerization can be prepared *in situ* by mixing a hydroxyl(s)-containing drug with an active metal complex, such as a metal-amido [41,50]. If well designed, the *in situ* formed M–ORs can initiate controlled polymerization of LA, resulting in quantitative incorporation of OR with 100% monomer conversion (Figure 7.3b) [41,46]. By judicious control of the metal catalyst ligand, it is also possible to control the regioselective coordination of a structurally complex drug molecule bearing multiple hydroxyl groups (Figure 7.2d). After ROP, the linear PLA will be covalently linked onto the specific hydroxyl group of the drug via an ester bond. PLA–drug conjugates can then be driven to form NPs—called nanoconjugates (NCs)—by nanoprecipitation methods (Figure 7.3c). Unlike nanoencapsulates, the use of a degradable ester linkage between a drug and a polymer prevents burst release from the NPs and facilitates the controlled release of drugs from the conjugates.

ROP of LA to generate polymer–drug conjugates with precise and homogenous chemistry has been examined in several studies performed by the Cheng laboratory [10,51,52]. For these studies, the ROP of LA was catalyzed by (BDI-X)MN(TMS)$_2$ (BDI = 2-((2,6-dialkylphenyl)amino)-4-((2,6-dialkylphenyl)imino)-2-pentene, M = Mg or Zn, Table 7.1), a class of catalysts developed by Coates and coworkers for the controlled ROP of LA [41,50]. The strategy allows for quantitative incorporation of multihydroxyl drugs [51] (e.g., paclitaxel (Ptxl), docetaxel (Dtxl), and doxorubicin (Doxo)), other hydroxyl-containing therapeutic molecules [52] (e.g., camptothecin (Cpt), cyanine, cyclopamine) and even small peptides (goserelin) via ester bonds. By tuning the substituents on the *N*-aryl groups ($R_1$ and $R_2$) and the β-position ($R_3$) of

**TABLE 7.1 (BDI-X)ZnN(TMS)$_2$ for NCs Synthesis**

| | Ligand | $R_1$ | $R_2$ | $R_3$ |
|---|---|---|---|---|
|   (BDI-**X**)ZnN(TMS)$_2$ | BDI-II | *i*Pr | *i*Pr | H |
| | BDI-EE | Et | Et | H |
| | BDI-EI | Et | *i*Pr | H |
| | BDI-IICN | *i*Pr | *i*Pr | CN |

the BDI ligand (Table 7.1) [53], regioselective polymerization on specific hydroxyl groups can be achieved (Table 7.2). The controlled polymerization also can be expanded to other biopolymers, such as poly(δ-valerolactone), poly(trimethylene carbonate), and poly(ε-caprolactone) (Table 7.3 for various polymers loaded with Ptxl and Dtxl). Apart from their controlled chemistry, drug–PLA conjugates can be nanoprecipitated to generate NPs with sub-120 nm diameter, high drug loading, nearly quantitative loading efficiencies, controlled release profiles without burst release, and narrow particle size distributions [51,52,54,55].

The controlled chemistry mentioned earlier was validated in the synthesis of Ptxl–PLA, and Doxo–PLA NCs. In the following discussion of these NCs, we examine the catalyst metal selection to achieve selective activation of hydroxyls in Cpt without disrupting the lactone ring structure [54]. Regioselective polymerization chemistry is also explored in the synthesis of Ptxl–PLA and Doxo–PLA NCs, whose initiator drugs possess multiple hydroxyl groups as well as other functional moieties. Combined, these experiments demonstrate that the proposed NC synthetic strategy is widely applicable for the synthesis of drug–polymer conjugates with various hydroxyl-containing therapeutics and with various polymer backbones.

### 7.3.2 Synthesis of Cpt–PLA Nanoconjugates

20(*S*)-Camptothecin (Cpt), a topoisomerase I inhibitor isolated from the Chinese tree *Camptotheca acuminate*, exhibits a broad range of anticancer activity in various animal models [56,57]. In terms of usability, Cpt has low aqueous solubility in its therapeutically active lactone form and is transformed rapidly to its carboxylate analog at physiological pH, producing a highly toxic and therapeutically inactive molecule (Figure 7.4a) [58,59]. While Cpt–polymer conjugates have been prepared to overcome the solubility limitation of the drug, conjugates prepared with conventional coupling chemistry are plagued by various heterogeneities. For example, experiments exploring the conjugation of Cpt via condensation reactions yield MWDs over a range 1.5–2.5 [16]. Meanwhile, direct conjugation of Cpt through its C20-tertiary hydroxyl is a difficult multistep reaction: Cpt must first be converted to a Cpt–amino ester and then conjugated to a polymer containing carboxylate groups via the amine end group of the Cpt–amino ester [16,60]. If the polymer has pendant functional groups, Cpt conjugation is further complicated.

To synthesize Cpt–PLA NCs via ROP, we first explored its ability to form Cpt–metal complexes with various BDI catalysts. When mixed with (BDI-II)MgN$(TMS)_2$, the C20-OH of Cpt formed a (BDI-II)Mg-Cpt alkoxide *in situ*. ROP of LA with this complex resulted in 100% LA conversion. HPLC analysis showed that Cpt was entirely conjugated to PLA with no detectable free Cpt in the polymerization solution. Although the $M_n$ of the resulting polymer was in good agreement with the expected $M_n$, the MWD of Cpt–$LA_{100}$ was relatively broad (1.31) due in part to chain transfer during polymerization [41]. In order to achieve a better controlled polymerization, we next tested (BDI-II)ZnN$(TMS)_2$. However, the (BDI-II)ZnN$(TMS)_2$/Cpt-mediated ROP resulted in only 61% Cpt incorporation, indicating inefficient formation of Cpt–Zn complexes during the initiation step (Table 7.4)

**FIGURE 7.4** (a) Equilibrium of Cpt Lactone and carboxylate forms. (b) Suggested insertion-coordination mechanism of (BDI)Zn-OR mediated ring-opening of lactide (LA) and succinic anhydride (SA). R group represents the PLA polymer chain or agents containing hydroxyl group(s) (e.g., Cpt).

[54]. The insufficient activation of the C20-OH of Cpt by (BDI-X)Zn was addressed by subtly tuning the 2- and 6-substituents of the *N*-aryl groups on the catalyst. Doing so, 100% incorporation efficiencies were observed in both (BDI-EE)ZnN(TMS)$_2$/Cpt- and (BDI-EI)ZnN(TMS)$_2$/Cpt-mediated polymerizations (Table 7.4) [54].

MWD, molecular weight distribution.
[a]Determined by HPLC analysis of Cpt–SA reaction mediated by different metal catalysts. The Cpt–carboxylate form indicated that the catalyst might have deleterious effect toward Cpt.

In addition to concerns regarding the ROP of LA, we also examined the retention of the lactone ring of Cpt throughout polymerization. As mentioned earlier, the lactone ring of Cpt is unstable and subject to ring opening in the presence of a nucleophile. To ensure that the therapeutically active form of Cpt is released in physiological conditions, the lactone ring of the drug must be maintained throughout the conjugation reaction. As LA is subject to rapid polymerization and the resulting Cpt–PLA conjugate is difficult to be characterized precisely, we used succinic anhydride (SA) as a model monomer to study (BDI-X)ZnN$(TMS)_2$/Cpt-mediated initiation. The ring opening of SA follows the same coordination–insertion mechanism as the initiation step of LA ROP but does not involve the subsequent chain propagation. Thus, the resulting product, Cpt–succinic acid (Cpt–SA), is a small molecule instead of a polymer. As a small molecule, the structure of Cpt–SA can be determined by routine characterization methods (Figure 7.4b). Experiments with SA revealed that Cpt activation by (BDI-II)MgN$(TMS)_2$ resulted in Cpt lactone ring opening (Table 7.4) [54]. The catalyst (BDI-EI)ZnN$(TMS)_2$, however, was able to prevent Cpt carboxylate formation. Using this catalyst, controlled polymerizations were observed over a broad range of LA/Cpt ratios from 75 to 400 in excellent agreement with the expected MWs and with narrow MWDs (1.02–1.18) [54].

With enhanced polymerization chemistry, Cpt–PLA NCs have improved formulation properties. Because both monomer conversion and drug incorporation are quantitative in Cpt–PLA synthesis, drug loadings can be predetermined by adjusting LA/Cpt feeding ratios. At a low monomer/initiator (M/I) ratio of 10, the drug loading can be as high as 19.5% (Cpt–$LA_{10}$, Table 7.2). To our knowledge, this Cpt–PLA NC has one of the highest loadings of Cpt ever reported [54]. Even at this high drug loading, sustained release of Cpt from Cpt–$LA_{10}$ NC was observed through the hydrolysis of the ester linker that connects the Cpt and the PLA without any observed burst release. Furthermore, the released Cpt (in PBS) had an HPLC elution time identical to authentic Cpt and was confirmed to have an identical molecular structure after isolation and characterization by $^1$H NMR [54]. In contrast, PLA/Cpt NPs prepared by co-precipitation have been previously reported to give low drug loading (0.1–1.5%), low loading efficiency (2.8–38.3%), and poorly controlled release kinetics (20–90% of the encapsulated Cpt released within 1 h in PBS) [61]. Our unique conjugation technique allows for formation of Cpt-containing PLA NCs with superbly controlled formulation parameters, thus making Cpt–PLA NCs potentially useful agents for sustained treatment of cancer *in vivo*.

### 7.3.3 Synthesis of Ptxl-PLA (Dtxl-PLA) Nanoconjugates

Initially isolated from the bark of the yew tree, Ptxl is a potent anticancer drug that was originally used as a treatment for ovarian and breast cancer. Its use has since expanded and the drug is now also used to treat lung, liver, and other types of cancer. Clinical application of Ptxl is often accompanied with severe, undesirable side effects partially due to the solvent Cremophor EL in the commercial formulation of Taxol$^{TM}$. To reduce the side effects, various nanoparticulate delivery vehicles have been developed and investigated in the past few decades [62–65], including

the FDA-approved albumin-bound Ptxl NPs (Abraxane™). Ptxl's analog, Dtxl (Taxotere™), is currently one of the best-selling chemotherapeutic agents and is used in the treatment of breast, ovarian, prostate, and nonsmall cell lung cancer. Many current NP formulations of both taxanes typically have low drug loadings, uncontrolled encapsulation efficiencies, and significant drug burst release effects when used *in vivo* [10,13,66,67]. Adding to formulation troubles, the densely functionalized structures of both molecules make it difficult to produce homogeneous Ptxl– and Dtxl–polymer conjugates.

Ptxl has three hydroxyl groups at its C2′, C1, and C7 positions which can initiate LA polymerization, resulting in Ptxl–PLA conjugates with 1–3 PLA chains attached (Figure 7.5a). The three hydroxyl groups differ in steric hindrance in the order of 2′-OH < 7-OH < 1-OH. The tertiary 1-OH is least accessible and is typically inactive [68]. The 7-OH, however, can potentially compete with 2′-OH [69] for coordination with metal catalysts. In order to differentiate the initiation site between the two hydroxyl groups, we postulated that a metal catalyst with a bulky chelating ligand would preferentially form Ptxl–metal complexes through the 2′-OH for site-specific LA polymerization.

A selective reduction reaction was used to divide Ptxl into two fragments—one with the 2′-OH and the other with the 1- and 7-OHs—in order to study the impact of catalyst on regioselectivity [70]. Tetrabutylammonium borohydride ($Bu_4NBH_4$) can selectively and quantitatively reduce the C13-ester bond of Ptxl to produce baccatin III (BAC) and (1*S*,2*R*)-*N*-1-(1-phenyl-2,3-dihydroxypropyl)benzamide (PDB; Figure 7.5a) [70]. Thus, Ptxl–$LA_5$ was generated using a variety of catalysts, reduced with $Bu_4NBH_4$ and examined using HPLC–MS analysis. Doing so, we found that Mg $(N(TMS)_2)_2$—a catalyst without a chelating ligand—initiates polymerization nonpreferentially at both the 2′-OH and the 7-OH. Its counterpart with a bulky BDI-II ligand (e.g., (BDI-II)$MgN(TMS)_2$) preferentially initiates polymerization at the 2′-OH position. However, the resulting Ptxl–PLAs displayed fairly broad MWD (>1.2). We reasoned that the observation was attributable to fast propagation relative to initiation for the Mg catalysts [41]. Thus, to reduce the MWD of polymers, we utilized a zinc analog, (BDI-II)$ZnN(TMS)_2$, to give a more controlled LA polymerization with a narrow MWD (1.02, Figure 7.5b) [41].

We further examined the effect of the ligand on initiation regioselectivity and LA polymerization by (BDI-X)$ZnN(TMS)_2$/Ptxl by varying the steric bulk of the *N*-aryl substituents ($R_1$ and $R_2$) and the electronic properties of $R_3$ (Table 7.5) [41,53,71,72]. While both PDB–PLA and BAC–PLA are observed for Ptxl–$LA_5$ initiated by (BDI-EE)$ZnN(TMS)_2$/Ptxl, analysis of the fragments of the reductive cleavage of (BDI-EI) $ZnN(TMS)_2$/Ptxl showed relatively reduced amounts of BAC–PLA. This indicates that a Zn catalyst with bulky *N*-aryl substituents will preferentially coordinate with the 2′-OH of Ptxl to initiate PLA polymerization. Of note, various studies suggest that the polymerization process does not lead to deleterious effect on Ptxl—the Ptxl can be loaded and released with intact structure.

SA was again used as a model monomer to study the initiation step of ROP. Such reactions yield a small molecule, Ptxl–succinic acid (Ptxl–SA), whose structure can be determined easily by routine characterization methods (Table 7.5). The results

**FIGURE 7.5** (a) $Bu_4NBH_4$-induced site-specific degradation of Ptxl for the formation of PDB and baccatin (BAC). (b) Scheme of Ptxl–PLA conjugates mediated by different catalysts, with the indication of regioselectivity and molecular weight distributions (MWDs).

show that the regioselectivity of the Ptxl/SA reaction increases as the sizes of $R_1$ and $R_2$ increase, in good agreement with the reductive reaction study using $Bu_4NBH_4$. The catalyst (BDI-II)ZnN(TMS)$_2$ showed the best regioselectivity while (BDI-EE) ZnN(TMS)$_2$ showed the worst. Changing $R_3$ from –H (BDI-II) to the electron-withdrawing –CN group (BDI-IICN) did not change the regioselectivity of the Ptxl/SA reaction. However, the addition of the CN group enhanced the reactivity of the resulting catalyst ((BDI-IICN)ZnN(TMS)$_2$), leading to a higher yield of Ptxl–2′-SA (Table 7.5). Controlled polymerization of PLA was observed when (BDI-II)ZnN

**TABLE 7.5 Regioselectivity of the Ptxl/Metal Catalyst-Mediated Ring Opening Reactions**

| Catalyst | Reduction of Ptxl–$LA_5$[a] | Ptxl–2′-SA (%) | Regioselectivity[a] | Regioselectivity for 2′-OH[b] | Polymer MWD |
|---|---|---|---|---|---|

| (BDI-EI)$ZnN(TMS)_2$ | Majorly PDB–LA, BAC | 45 | Majorly 2′-OH | 77 | ~1.2 |
| (BDI-IICN)$ZnN(TMS)_2$ | PDB–LA, BAC | 54 | 2′-OH | 100 | <1.1 |

[a]Determined by HPLC analysis of Ptxl–$LA_5$ site-specific reduced by $Bu_4NBH_4$.
[b]Determined by HPLC analysis of Ptxl–SA ring opening reactions mediated by (BDI-X)Zn catalyst.

$(TMS)_2$/Ptxl was used at various [LA]/[Ptxl] ratios (50/1–300/1), with the obtained MWs in excellent agreement with the expected MWs and the monomodal MWDs in the range of 1.02–1.09.

Dtxl, the Ptxl analog, has four hydroxyl groups at C2′, C1, C7, and C10 (Table 7.2). To examine the regioselectivity of Dtxl-initiated ROP of LA, we examined the Dtxl/(BDI-X)ZnN$(TMS)_2$-mediated ring opening reaction of SA. When complexed with (BDI-II)ZnN$(TMS)_2$, Dtxl reacted with SA to yield Dtxl–2′-SA with 100% regioselectivity and 71.5% yield. (BDI-II)ZnN$(TMS)_2$/Dtxl also showed excellent control for the ROP of LA, affording Dtxl–PLA with predictable MWs and very narrow MWDs. NCs formed with either Ptxl–PLA or Dtxl–PLA showed unprecedented high loading—up to 28.3 wt% in Ptxl–LA NCs and up to 35.9 wt% in Dtxl–LA NCs. The detailed formulation methods and efficacy of both conjugates are further discussed in Section 7.4.

Poly(δ-valerolactone) (PVL), poly(trimethylene carbonate) (PTMC), and poly (ε-caprolactone) (PCL) have been used extensively as alternatives to PLA in suturing, drug delivery, and tissue engineering applications. We were therefore interested as to whether the Ptxl (or Dtxl)/(BDI-II)ZnN$(TMS)_2$-mediated ROP of LA could be extended to the synthesis of Ptxl–PCL, Ptxl–PVL, and Ptxl–PTMC conjugates. Ptxl/(BDI-II)ZnN$(TMS)_2$ showed excellent control over the polymerization of δ-valerolactone (VL), trimethylene carbonate (TMC), and ε-caprolactone (CL). All the polymerization reactions gave drug–polymer conjugates with the expected MWs and narrow MWDs ($M_w/M_n < 1.2$) (Table 7.3). Furthermore, the polymerizations of VL and CL proceeded at room temperature, and the monomer conversions were quantitative. The polymerization of TMC, however, required a slightly elevated reaction temperature (6 h at 50°C).

### 7.3.4 Synthesis of Doxo–PLA Nanoconjugates

Doxo is commonly used in the treatment of a wide range of cancers and leukemia. Clinically, Doxo is administered as Doxil™, a PEGylated liposome-encapsulated form of the drug [74,75]. Owing to its high hydrophilicity, the encapsulation of Doxo within a hydrophobic polymer matrix can be challenging. For micelles formed by co-precipitating Doxo and PLGA–PEG, reported values indicate Doxo loading and loading efficiency as low as 0.51% and 23%, respectively [76]. Doxo loadings of 0.6–8.7% with loading efficiencies of 11.4–43.6% have also been reported by Hubbell and coworkers in their encapsulation studies using inverse emulsion polymerization of nonprotonated Doxo [77]. However, even with techniques allowing increased loading, burst release of Doxo is reported in many NP delivery systems [40,76,77].

Conjugation of Doxo to polymers can be difficult due to the diverse functional groups presented by the drug. Doxo has three hydroxyl groups, two phenolic hydroxyls, one ketone group, and one amine group. Doxo is also sensitive to pH, heat, metal ions, and light, further complicating its conjugation chemistry [78]. One conjugation strategy is to couple the terminal carboxylate of PLA with Doxo by creating an amide linkage through the 3′-$NH_2$ of Doxo [39,79]. Such Doxo–PLA conjugates, however, cannot release Doxo in its original form by hydrolysis.

Instead, Doxo-3′-lactamide, a prodrug of Doxo, is formed, which does not easily degrade *in vivo* due to the stability of amide bond [80]. Other efforts have been devoted to conjugation between the C13-ketone group of Doxo and hydrazine groups of polymeric carriers by forming an acid-labile hydrazone bond [22,81–83]. However, clinical studies of immunoconjugates with Doxo connected to monoclonal antibodies via hydrazone linkers gave unsatisfactory antitumor effects, ultimately leading to the termination of the clinical development of such immunoconjugates [84].

In previous studies involving the use of metal catalysts for LA polymerization, ROP of LA proceeded predominately by metal–alkoxides (M–ORs) rather than by metal-amides (M-NHRs) [47]. M–OR complexes typically have higher activities for LA ring opening than their amine analogs. For instance, Coates and coworkers reported that (BDI)ZnOCH$(CH_3)_2$ initiated and completed an LA polymerization within 20 min at a M/I ratio of 200 while a similar polymerization mediated by (BDI) ZnN$(TMS)_2$ required 10 h to complete [41]. The chemoselectivity of -OH instead of -$NH_2$ for Zn catalysts has also been confirmed by another molecular pair, 1-pyrenemethanol (Pyr-OH) and 1-pyrenemethylamine (Pyr-$NH_2$) [52].

Doxo has three hydroxyl groups, one at each of its C4′, C9, and C14 positions. Theoretically, LA polymerization can be initiated by any or all of these hydroxyl groups. C9-OH is the most sterically hindered and thus unlikely to initiate polymerization. To evaluate the initiation regioselectivity, we mixed Doxo with the catalyst (BDI-II)ZnN$(TMS)_2$ and succinic anhydride (SA) to mimic the initiation step of LA polymerization. ESI–MS results coupled with NMR analysis revealed that the SA ring was opened by the C14-OH of Doxo rather than by the C4′-OH or C3′-$NH_2$ of Doxo. When (BDI-II)ZnN$(TMS)_2$ was replaced by Zn$(N(TMS)_2)_2$, a Zn catalyst without ligands, the initiation regioselectivity completely disappeared, with Doxo–4′, 14-bissuccinic ester (Doxo–2SA), and Doxo–4′, 9, 14-trisuccinic ester (Doxo–-3SA) being the predominant products (Figure 7.6). Interestingly, the metal activity also had a profound effect on regioselectivity. When the more highly active (BDI-II) MgN$(TMS)_2$ catalyst was used in a similar reaction, the most prevalent product was Doxo–2SA. Thus, by rationally designing ROP metal catalysts, Doxo–PLA conjugates with highly controlled regio- and chemoselectivity are achievable within one step without having to protect the C3′-$NH_2$ and other competing hydroxyl groups of Doxo [52].

Having completed preliminary investigations with SA, we next studied Doxo-initiated LA polymerization. Doxo/(BDI-II)ZnN$(TMS)_2$-mediated LA polymerization resulted in Doxo–PLA with narrow MWD ($<1.2$) and the expected MWs. At a low M/I ratio of 10, the drug loading was as high as 27.4% (Doxo–$LA_{10}$). To our knowledge, this is by far the highest loading ever reported in Doxo-containing polymeric NPs [52]. HPLC analysis revealed that Doxo–$LA_{10}$ conjugates incubated in PBS at 30°C released Doxo in its original, therapeutically active form. In a separate experiment, Doxo–$LA_{100}$ treated with 0.1 M NaOH was shown to release 88–92% of the Doxo in its original form. In this case, the incomplete recovery is likely due to instability of Doxo in NaOH. Combined, these studies suggest that Doxo molecules were linked to PLA through its hydroxyl group(s) by forming ester linker(s) with PLA, which could be hydrolyzed in an alkaline condition. Even at high

**FIGURE 7.6** Scheme of Doxo–SA reaction (1:3 molar ratio) mediated by different Zn catalysts.

drug loading (27.4%), sustained release of Doxo from Doxo–$LA_{10}$ NC was observed without burst release. This is in sharp contrast to the burst release of PLA/Doxo NPs prepared by co-precipitation, in which 90% of the Doxo is released within 3 h [52]. The sustained release of Doxo from NCs with high loading may help alleviate the systemic side effects of Doxil$^{TM}$ without reducing the overall dosage.

## 7.4 NANOCONJUGATES: FORMULATION AND POTENTIAL APPLICATION

### 7.4.1 Formulation

Particle size is an important aspect of drug delivery. For cancer therapeutics, formulated particles should have a uniform, monomodal distribution and a diameter <200 nm to take advantage of the enhanced permeability and retention (EPR) effect. As such, particles formed by nanoprecipitation of Ptxl–PLA were evaluated for their size. In general, Ptxl–PLA yielded particles with monomodal distributions while their nanoencapsulate (NEs, see Section 7.2.1) counterparts were polydisperse (Figure 7.7a) [13,85]. As the multimodal distribution of NEs is due in part to the aggregation of nonencapsulated free drug [13], the monomodal distribution observed with NCs is likely related to the unimolecular structure of Ptxl–PLA conjugates. The actual size of Ptxl–PLA NPs prepared by nanoprecipitation can be manipulated by changing the solvent as well as polymer concentration. At a fixed Ptxl–PLA concentration, the size of NCs prepared by precipitating a DMF solution of conjugate

**FIGURE 7.7** (a) Ptxl–$LA_{25}$ NCs were analyzed by dynamic light scattering (DLS) and scanning electron microscopy (SEM). (b) SEM image of Ptxl–$LA_{25}$/PLGA–mPEG NCs (Scale bar = 150 nm). The different density of materials were indicated with different gray scale: PEG layer (white color) and hydrophobic PLA part (gray color) (c) Release kinetics of Ptxl from Ptxl–PLA NCs and Ptxl–PLA NE (Prepared by nanoprecipitation of a mixture of Ptxl and PLA (Ptxl–PLA (wt/wt) = 1/12) at 37°C in PBS. (d) $IC_{50}$ values determined by MTT assay of Ptxl–PLA NCs and free Ptxl, which were incubated with PC-3 cells for 24 h. (*Source*: Figures reproduced with permission from Reference [51].)

is typically in a range 60–100 nm, 20–30 nm smaller than those prepared with acetone or THF as a solvent [13]. When nanoprecipitation is carried out using a 1:20 (v:v) mixture of DMF and water, the size of Ptxl–LA NCs shows a linear correlation with the conjugate concentration and can be used to precisely form particles with diameters from 60 to 100 nm.

Surface modification of NPs with PEG is widely used for prolonged systemic circulation and reduced aggregation of NPs in blood [86]. To avoid the removal of unreacted reagents and by-products, poly(lactide)-*b*-methoxylated PEG (PLA–mPEG)—an amphiphilic copolymer that has a 14 kDa PLA and a 5 kDa PEG segment [87]—was used to PEGylate NCs instead of covalently conjugating PEG to NCs [65,85]. The PEGylated structure of the NCs can be seen by scanning transmission electron microscopy (Figure 7.7b). Ptxl–LA NCs with a PEGylated surface have a negative surface zeta potential and thus remain nonaggregated in water and PBS solution by means of surface charge repulsion. In addition, we also

developed a one-step co-precipitation method to formulate NCs that could stay nonaggregated in a salt solution with an amphiphilic triblock copolymer PLA–PEG–PLA, a feature that diblock PLA–PEG did not provide [55].

Drug burst release is a long-standing formulation challenge to NEs and often results in undesirable side effects and reduced therapeutic efficacy [67]. Conventional NEs typically show burst release of 60–90% of their payload within a few to tens of hours [9]. Since the Ptxl release kinetics of Ptxl–PLA NCs is determined not simply by diffusion—as is the case with NEs—but by the hydrolysis of the Ptxl–PLA ester linker followed by diffusion out of NCs, the release kinetics of Ptxl from NCs are more controlled and show significantly reduced burst release (Figure 7.7c). For example, Ptxl released from Ptxl–$LA_{25}$ NCs (19.2 wt%) was 8.7% at Day 1 and 70.4% at Day 6. In comparison, 89% of Ptxl was released within 24 h from Ptxl/PLA NE (Figure 7.7c). Release of Ptxl from Ptxl–$LA_{50}$ NCs was slower than from Ptxl–$LA_{25}$ NCs, presumably because of the higher MW of Ptxl–$LA_{50}$ and more compact particle structure. With its controlled drug release, the *in vitro* toxicity of Ptxl–LA NCs correlates with the amount of Ptxl released (Figure 7.7d). For example, Ptxl–$LA_{15}$ NCs have a nearly identical $IC_{50}$ to free Ptxl (87 nM) while the $IC_{50}$ of Ptxl–$LA_{50}$ NCs is an order of magnitude higher. As a result, the toxicity of NCs can be tuned in a wide range simply by controlling NC drug loading.

Aptamers are either single-stranded DNA or RNA that specifically binds to target ligands [88,89]. When used for cancer targeting, aptamers are capable of binding to target antigens with extremely high affinity and specificity in a manner resembling antibody-mediated cancer targeting [90,91]. Unlike antibodies, synthesis of aptamers is an entirely chemical process and thus shows negligible batch-to-batch inconsistency [92,93]. Moreover, aptamers are typically nonimmunogenic and exhibit remarkable stability against pH, temperature, and solvent. The A10 aptamer with 2′-fluoro-modified ribose on all pyrimidines and a 3′-inverted deoxythymidine cap has been identified and utilized to target extracellular prostate-specific membrane antigen (PSMA) [94]. A10 binds to PSMA-positive LNCaP prostate cancer cells but not PSMA-negative PC-3 prostate cancer cells. To demonstrate NC targeting, amine-terminated A10 aptamer was conjugated to PLA–PEG–COOH/Cy5–PLA NCs through carboxylic acid–amine coupling in the presence of EDC and NHS to give aptamer/PLA–PEG–COOH/Cy5–PLA NCs (aptamer–Cy5 NC) [90]. Incubation of aptamer–Cy5 NCs with LNCaP cells for 6 h resulted in substantially increased NC internalization (Figure 7.8) compared to PC-3 cells. These *in vitro* studies demonstrated that NCs conjugated with aptamer-targeting ligand can potentially be used for prostate cancer targeting.

Small-scale NPs that stay nonaggregated in PBS for *in vitro* or *in vivo* laboratory studies are straightforward. However, in order to facilitate clinical translation, NPs need to be prepared in large quantity with well-controlled properties that remain unchanged during the processes of manufacturing, storage, and transport. Because Ptxl is covalently conjugated to PLA through an ester bond that is subject to hydrolysis upon exposure to water, handling of Ptxl–PLA NCs in aqueous solution is undesirable. Thus, NCs have to be formulated in solid form for clinical use. By screening various molecules, we discovered that albumin functions as an excellent

**FIGURE 7.8** Confocal images of LNCaP (a) and PC-3 (b) cells treated with aptamer-functionalized nanoconjugates (NC–Apt, top) and nanoparticles without aptamer (NC, bottom).The Cy-5 incorporated NC or NC–Apt are shown in red. The cells counter stained with Alexa-Flour 488 Phalloidin (binding to cellular actin) are shown in green.

lyoprotectant for Ptxl–PLA and yields solid NCs that do not aggregate when reconstituted in PBS. By incorporating the albumin-based lyoprotection technique, we demonstrated for the first time that polymer nanoparticles containing a conjugated nucleic acid targeting ligand can be prepared in solid form and still be reconstituted to well-dispersed, nonaggregated particles with functional targeting capability [55].

### 7.4.2 Theranostic Nanoconjugates

There is growing interest in developing noninvasive, whole-body fluorescent imaging techniques to assess the biodistribution of drug delivery systems or diagnostic agents within patients. To ensure effective measurement of fluorescent signal *in vivo*, it is crucial to use red or near-IR dyes. Quantum dots, a class of inorganic nanocrystals with excellent fluorescent intensity and photostability, can readily be prepared to have a far-red emission band. However, there is a general consensus

**FIGURE 7.9** Distribution of Cy5 dye-labeled PLA NCs in various visceral mice organs. Mice were sacrificed 24 h after i.v. injection of Cy5–PLA NCs.

that quantum dots cannot be used in humans because of their toxicity. Currently, small molecule organic dyes are more promising probes to be coupled with imaging systems for clinical applications as compared to quantum dots. Polymeric nanoparticles can function as good carriers for the delivery of small molecule imaging materials because they can provide prolonged systemic circulation and improved tumor accumulation compared to unformulated drugs. To meet this challenge, it is particularly important that NPs be formulated with stably incorporated fluorescent ligands and controlled formulation parameters (size, surface properties, etc.). Accordingly, our monomodal, narrowly distributed PEGylated Cy5–PLA NPs have the potential to be candidates for whole body *in vivo* imaging. Preliminary *in vivo* studies demonstrated that Cy5–PLA NCs can be easily visualized in various visceral organs with low autofluorescent background ratios (Figure 7.9). Owing to their sub-100 nm size, the Cy5–PLA NCs also can be used to study the lymphatic biodistribution of NPs when coupled with whole-body optical imaging [95]. These promising results support the further development of Cy5–PLA NCs as a model system to assess the *in vivo* pharmacological and pharmacokinetics profiles of NCs.

### 7.4.3 Nanoconjugates Against Other Diseases

Considering that molecular targeting of cell-based targets may be confounded by inter- or intra-patient heterogeneity in cell surface antigen expression, targeted NPs that can recognize the extracellular matrix have attracted considerable attention for

therapeutic/diagnostic delivery. We have recently engineered a peptide-conjugated NP to target the vascular basement membrane for the treatment of injured vasculature. The high affinity C11 peptide was screened from a combinatorial phage library of hepta-peptide ligands against human collagen IV, which represents 50% of the vascular basement membrane (Figure 7.10) [96]. Angioplasty-injured carotid artery

**FIGURE 7.10** (a) Schematic of NPs synthesis by nanoprecipitation and self-assembly of Ptxl–LA NCs with lipids and peptide ligands to adhere to the exposed basement membrane during vascular injury. (b) Scheme of *ex vivo* abdominal aorta injury model; samples were delivered into the aorta segment for 5 min. (c) Fluorescence images overlaid on photographs of balloon-injured aortas incubated with NCs with a targeting peptide, compared with scrambled-peptide and nontargeted NPs. (d) *In vivo* intra-aortic administration in a carotid injury model: a catheter was inserted via the external carotid into the common carotid and advanced into the aortic arch. (e) Fluorescence images overlayed on photographs of carotid arteries incubated with NCs with a targeting peptide, compared with scrambled-peptide and nontargeted NPs. (f) *In vivo* systemic administration in a carotid angioplasty model. (g) Fluorescence images overlayed on photographs of carotid arteries incubated with NCs with a targeting peptide, compared with scrambled-peptide and nontargeted NPs. For imaging, Alexa Fluor 647–PLGA dye conjugates were encapsulated in place of Ptxl–PLA drug conjugates. (Scale bar, 1 cm.)

was used as a model of compromised vasculature to examine the targeting capacity of the C11 peptide-conjugated polymeric NPs. The targeted NPs were delivered via both intra-arterial and i.v. administration and, when compared to nontargeted NPs, showed greater *in vivo* vascular retention at sites of injured vasculature in rats (Figure 7.10) [96]. Although the initial application was for vessel wall targeting in cardiovascular disease, the utility of this peptide-targeted NP system is broad and could be used to diagnose and treat different human diseases where the endothelial lining is compromised.

Immunosuppressive agents have played a pivotal role in ensuring the success of organ transplantation and greatly improved the outcomes of patients with life-threatening, immune-mediated diseases [97]. However, the use of immunosuppressive agents is hindered by the lack of selectivity as well as major adverse drug reactions. The immunosuppressive agent cyclosporine (CsA), for example, results in a dramatic improvement in short-term allograft survival but also poses a risk of chronic nephrotoxicity because of its narrow therapeutic window [98–100]. We recently developed CsA–PLA NCs to achieve targeted immunosuppression for a wide variety of immune-mediated disorders [101]. CsA–PLA NCs showed superior physicochemical properties with excellent size control, narrow size distribution, and very well controlled release kinetics without a noticeable burst release. CsA–PLA NCs also showed excellent stability in biological media with negligible aggregation. Because of their ability to mediate the sustained release of CsA *in vitro* while suppressing T-cell mediated immune responses, CsA–PLA NCs are an excellent system for immunosuppression of organ rejection. We also developed a novel strategy combining CsA–PLA NCs with dendritic cells (DCs) to efficiently deliver CsA to draining lymph nodes to inhibit T-cell priming in a locally controlled and sustained manner without systemic release. This innovative delivery strategy constitutes a strong basis for future targeted delivery of immunosuppressive drugs with improved efficiency and reduced toxicity.

## 7.5 CONCLUSIONS AND OUTLOOK

LA ROP-mediated drug conjugation allows for facile regio- and chemoselective incorporation of drugs onto PLA. This in turn allows for the formation of drug delivery vehicles with low polydispersity, predetermined drug loadings (up to ~30%), and quantitative loading efficiencies. The BDI–metal chelating complexes described earlier for Cpt, Ptxl, and Doxo conjugation do not have deleterious effects on drugs and can be easily removed by solvent extraction. Because both Zn and Mg ions are biocompatible and, in fact, are key elements in our dietary mineral supplements, there should be no significant safety concerns regarding the use of these two metal catalysts. Multigram scales of drug-PLA conjugates can be readily prepared within hours using the one-pot polymerization approaches described here. Because drug molecules are covalently conjugated to PLA, the post-reaction formulation process (precipitation, removal of catalysts, nanoprecipitation, sterilization, lyophilization, shipping and handling, etc.) has minimal impact on sample

property as compared to drug–polymer NPs prepared via encapsulation methods. This polymerization-mediated conjugation method may be utilized for the formulation of polymer–drug conjugates not only for drug delivery, but also for other controlled release applications (scaffolds, coatings of stents, etc.). Other cyclic esters (e.g., ε-caprolactone and δ-valerolactone) are likely to replace LA and find use as monomers in such drug-initiated polymerizations [102]. The drug/(BDI-X) $ZnN(TMS)_2$-initiated polymerization of these cyclic esters at room temperature has recently been achieved in our laboratory, which will provide further tunability of the release profiles and other physicochemical properties. Given that the lack of a controlled formulation for nanoparticulate drug delivery vehicles is one of the bottlenecks to their clinical development, this unique, ROP-mediated conjugation methodology may contribute to the development of clinically applicable nanomedicines.

Although there has been impressive progress in nanomedicine for cancer treatment in the past few years, enormous tasks remain. The convergence of seemingly disparate scientific fields (e.g., cancer biology, electronics, bioimaging, biomicroelectromechanical systems, computer science, polymer and materials chemistry, biophysics) will only accelerate the development of nanomedicine [103]. Our work will continue in the daunting task of pushing targeted nanoconjugates for clinical evaluation, with the expansion of our technology to other disease-related formulations (e.g., imaging agents or implantable devices). It also will be important to improve intratumoral penetration for enhanced efficacy [104,105]. Given the limitations of spatial and temporal changes in the expression of the target [106], the seemingly pedestrian issues on targeting ligand functionality are also likely to be challenging *in vivo* [107,108]. The prevention and treatment of metastasis will be of particular interest because metastasis is responsible for 90% of cancer deaths [109]. The coordination of different approaches will help optimize the delivery efficiency. A deep understanding of all aspects of the biology of cancers, including tumor microenvironment, will continue to be crucial for design and understanding [110]. We are far from being able to create delivery vehicles to meet the expectation of complete tumor eradication. However, as the field of nanomedicine matures, the objective may be on the horizon.

## 8.1 INTRODUCTION

It is estimated that two-thirds of the newly synthesized drugs are poorly soluble in water [1]. Delivery of these compounds requires significant efforts and, in some cases, becomes extremely difficult. Poor solubility limits the bioavailability when delivered through the oral route; for many compounds, parental delivery, which requires special formulation treatment to overcome the solubility limit, remains to be the only choice. A common practice is to solubilize a poorly soluble drug with specialized organic molecules, which include organic solvents, surfactants, and macromolecules. Unfortunately, adverse effects resulted from the use of such solubilizing molecules, for example, hypersensitivity reactions, nephrotoxicity, neurotoxicity, and neutropenia, have been reported [2,3]. In addition, the individually solubilized drug molecules can also reach healthy organs and tissues indiscriminately and inflict undesired effects. Hence, there is a need for developing formulation that can deliver poorly water-soluble drugs, including anticancer agents.

Attempting to target tumors, anticancer drugs are generally formulated as nanoparticles in order to take advantage of the so-called enhanced permeability and retention (EPR) effect [4], which characterizes tumors' underdeveloped vasculatures and ineffective lymphatic systems. Various nanosized carrier designs have been developed, including liposomes [5,6], micelles [7], solid lipid nanoparticles [8,9], polymeric nanoparticles [10,11], and dendrimers [12]. In many of these nanoparticle designs, drug molecules are solubilized, dispersed, and encapsulated by specialized chemicals.

Despite a significant amount of efforts on the development of new delivery systems over the last few decades, there are only a few Food and Drug Administration (FDA)-approved cancer therapy products in which poorly soluble drugs are formulated as nanoparticles. Two are liposomal formulations, Doxil® (doxorubicin) and Daunosome® (daunorubicin), and one other is Abraxane®, albumin-bound paclitaxel (PTX) nanoparticles. Impeding the progress in the anticancer drug product development are several factors that lie in the current formulation design strategy. When a drug is solubilized into a nanoconstruct, the multicomponent system is prone to physical instability and structural destruction during storage and/or *in vivo* passage, resulting in drug leakage [13,14]. The drug loading is typically limited [7,15]; high manufacturing cost, multiple steps in preparation and synthesis, and difficulties in scale-up have also limited the potential of the aforementioned vehicles for clinical usage.

Clearly, it has been and will remain a significant challenge to deliver a poorly soluble anticancer compound. Current solubilization approaches face inherent limitations that need to be overcome for the clinical application, particularly when tumor targeting is desired. It is recognized that in order to fully take advantage of the EPR effect, a clinically viable tumor-targeted delivery system has to be stable, should have a high drug loading, and be capable of sustaining the release of drug molecules in the tumor [16]. It is rather futile to develop an intricate vehicle that has little clinical potential. New approaches need to be developed to shift the paradigm of delivering poorly soluble drugs, including antineoplastic agents.

Over the last few years, nanocrystal formulations have been of considerable interest for delivering poorly soluble drugs via oral, parenteral, and other routes [17]. Administered directly as nanosized solid particles, drug nanocrystals require no solubilizing and/or encapsulating chemicals, thus circumventing side effects and instability drawbacks impeding many existing delivery systems. More importantly, production of nanocrystals at the large scale is feasible due to the simplicity of formulation and absence of solubilizing, encapsulating, or conjugating steps. Nanocrystals are expected to target the tumor via the EPR effect and offer less toxicity, improving the anticancer efficacy and pharmacokinetic properties. Nanocrystal formulations may likely rejuvenate the delivery of poorly soluble anticancer compounds, existing and to be discovered.

In this chapter, we first review the production of nanocrystals of pharmaceutical organic compounds. We then focus on the application of nanocrystals for cancer therapy.

## 8.2 NANOCRYSTAL PRODUCTION

Crystals are regular, periodic supramolecular structures assembled by organic or other types of molecules or atoms. Characteristically, a crystal shows distinct X-ray diffraction patterns, and has a specific melting point, density, and solubility, in addition to other well-defined physicochemical properties. Compared with the amorphous state, in which molecules are randomly packed, the crystalline state is more stable, exemplified by the fact that amorphous materials can readily undergo spontaneous phase transition and recrystallization. As such, using crystalline materials in a formulation assures better physical stability than amorphous formulations.

Nanocrystals of poorly soluble drugs can offer several advantages over solubilized and encapsulated formulations. Besides the physical stability, the dissolution rate of nanocrystals can be significantly enhanced—under sink condition—due to the increase in the surface area. More importantly, manufacturing at the industrial scale is possible. In the following sections, we discuss two major approaches for producing nanocrystals of organic molecules. The top-down approach processes large crystals and physically comminute into smaller pieces; the bottom-up approach yields nanocrystals from solution by crystallization. Several review articles have focused on the techniques, mainly the top-down approach [17–21].

### 8.2.1 Top-Down Approach

There are two basic diminution techniques: wet milling and high-pressure homogenization. Wet milling involves mechanical attrition, where drug particles are wetted by an aqueous solution of surfactants and subjected to shearing and grinding by mechanical toolings, such as milling balls in a milling container. The particle size is reduced and may reach a few hundred nanometers. The Nanocrystal® technique [22], a wet milling process patented by Élan Co., has yielded several oral products including Rapamune®, Emend®, Tricor®, and Megace ES® [23]. One drawback of the technique is potential contamination from the erosion of metal milling balls or pearls. The amount of contamination is determined by the hardness of drug particles as well as the milling time, which can take up to several days [24]. The use of polymeric beads (e.g., polystyrene derivatives) may be helpful in minimizing the erosion.

High-pressure homogenization is another fragmentation technique. One development is based on jet-stream microfluidization [25], in which two fluid streams of particle suspensions collide under high pressure in a Y-shaped chamber, leading to particle collision and subsequent particle rupture. The marketed product Triglide® developed by SkyePharma Co. is produced by Insoluble Drug Delivery-Particles (IDD-P™) technology, a microfluidization method [26]. Piston-gap homogenizers are also used to produce nanosized solid particles by forcing a suspension of drug particles with a piston through a thin gap under high pressure [27]. The combination of cavitations, high shear forces, and turbulent flow fractures the particles. The outcome of particle fragmentation is decided by several factors, including the power of homogenization, particle hardness, and number of the piston-moving cycles. Compared with wet milling, the homogenization method may yield less

contamination during the production process [28]. There are currently two patented technologies for nanocrystal production that employ the piston-gap homogenization method, DissoCubes® and Nanopure®. In the former, developed by SkyePharma Co., drug powders are dispersed in an aqueous solution of surfactants and subjected to homogenization [27]; in the latter, previously owned by PharmaSol GmbH and now acquired by Abbott Co., drug particles are suspended in either nonaqueous dispersion media (e.g., oils and liquefied polyethylene glycol) or aqueous-organic cosolvents (e.g., glycerol–water and ethanol–water mixtures) prior to homogenization [27]. These operations require that one starts with drug particles no larger than 25 μm so that the blockage of the homogenizer can be minimized [29].

Currently, the top-down approach dominates the production of nanocrystals and is used to manufacture several products on the market [21]. Despite its popularity, there are inherent drawbacks in this approach, including the high-energy input, prolonged operation time, possibility of contamination, and decreased crystallinity or stability [30]. The stability concern is particularly critical for a nanocrystal system to be considered for parenteral drug delivery. The amorphous content produced during the high-energy process can lead to phase instability, which in turn causes uncertainty and potential variability in pharmacokinetic behavior, which should be tightly controlled.

### 8.2.2 Bottom-Up Approach

Nanocrystals can be grown directly from solution. Nucleation and crystal growth thus play the essential role in the bottom-up approach. To induce nucleation, a solution needs to become supersaturated. Cooling, evaporating the solvent, and mixing with an antisolvent are among several ways to create supersaturation [31]. Still, a solution can become supersaturated to some extent without producing any nuclei. This is because nucleation is energetically unfavorable. According to the classical nucleation theory [32–34], the change in free energy when a nucleus starts to grow includes two energy components, one associated with the creation of the new surface, and another with the packing of molecules in the bulk crystal. As depicted in Figure 8.1, the surface-related term, $\Delta G_S$, is always positive (energetically unfavorable) because creation of a new surface of a solid particle requires energy input. On the other hand, the bulk-related term, $\Delta G_V$, is negative (energetically favorable) due to the formation of intermolecular interactions between molecules in the nucleus. When a nucleus is small, $\Delta G_S$ dominates, and the overall free energy change is positive so that the development of the nucleus is not spontaneous. As the nucleus grows and surpasses, the so-called critical nucleus size, $\Delta G_V$ becomes dominant and the overall term becomes negative. Subsequently, the nucleus can grow freely as long as supersaturation is maintained.

In reality, homogeneous nucleation—nucleation without the aid of substances other than the solute molecules—seldom occurs. Foreign materials, impurities, or even the surface of the crystallization vessel often help to induce nucleation, which is denoted as the heterogeneous nucleation [35]. According to the classical nucleation theory, the presence of a foreign surface lowers the $\Delta G_S$ term for a nucleus to form on

**FIGURE 8.1** The change in free energy as a function of crystal size during the nucleation and crystal growth process.

the surface. In other words, the nucleus requires less energy for surface creation when it forms on a pre-existing surface.

In order to produce nanosized crystals from solution, it is thus extremely critical to control the nucleation process. It is important not only for controlling the particle size but also for the size distribution. Ideally, nucleation of a large number of crystalline embryos must occur concurrently from the supersaturated solution. Rapid depletion of the solute molecules from the solution limits further growth of each nucleus so as to achieve a nanosize. Having a large number of nuclei produced at the same time also keeps the particle size distribution narrow. Similar particle sizes are not only preferred for ensuring product quality but also important for maintaining the stability of nanocrystals. A narrow distribution of particle size can greatly minimize the so-called Ostwald ripening phenomenon, in which larger particles grow at the expense of redissolving smaller ones because of their differences in surface energy [36]. For this purpose, the induction of nucleation needs to be abrupt and homogeneous throughout the growth medium. One common strategy is to mix the solution of a drug compound with an antisolvent so that the supersaturation is reached immediately; at the same time, the mixture is subjected to intense sonication and/or mechanical stirring. It is known that air cavities created by sonication may trigger nucleation because of the presence of air–liquid interfaces and locally concentrated liquid pockets. Nevertheless,

because nucleation is such a difficult process to control [37], subtle changes in growth conditions can result in drastic variations in product quality. For producing nanocrystals, extreme care is needed for identifying a suitable set of peripheral conditions [38], which mostly likely vary for distinct compounds. Figure 8.2 shows a few samples of nanocrystals that were produced by the bottom-up approach in our laboratory.

There are several approaches that have been developed to create supersaturation and induce nucleation [20]. They include hydrosols [36], high-gravity controlled

**FIGURE 8.2** SEM images of nanocrystals grown in our laboratory: camptothecin (a), paclitaxel (b), and ZSTK474 (c). Scale bar: 2 μm.

precipitation technology (HGCP) [39,40], confined impinging jets [41], supercritical fluid (SCF) technology [42], and sonoprecipitation [43], as discussed further.

***8.2.2.1 Hydrosols.*** Considered to be a more mature method, hydrosols or aqueous nanosuspensions of poorly water-soluble drugs have been developed by Sandoz (now Novartis) [44]. The active ingredient is dissolved in aqueous-organic miscible cosolvents (e.g., ethanol, isopropanol, and acetone), while various peptisers and/or stabilizing agents (e.g., citric acid, gelatin, ethyl cellulose N7, lecithin) may be added to the aqueous phase to prevent aggregation. A matrix former, generally sugar or sugar alcohol (e.g., mannitol), is also added to the solution to prevent agglomeration and aid in the resuspension process. In the laboratory setting, solid nanoparticles can be produced by mechanically mixing the various components in a beaker while removing the organic solvent through evaporation. For the industrial production, the organic and aqueous phases are pumped into a static mixer and forced through an atomizing nozzle, leading to the formation and drying of nanoparticles [44–47]. One study reported that spray-dried cyclosporin A contained 38 μm particle agglomerates that were then reduced to 120 nm upon redispersion in water [45]; the nanoparticles produced by this method were nonetheless amorphous [45,46].

***8.2.2.2 High-Gravity Controlled Precipitation (HGCP).*** HGCP is considered to be one of the most promising techniques to produce nanoprecipitations at the commercial scale [20]. The key component in HGCP is a rotating packed bed (RPB), where two liquid streams are pumped in and mixed together vigorously by centrifugation. Subsequently, the mixture is spread into thin films and ultimately broken into tiny droplets. In addition to using antisolvents, mixing two streams of reactants can also produce precipitates chemically in HGCP. Depending on the compound and conditions, a product may be amorphous or crystalline. Nanoparticles of a few pharmaceutical compounds, including cephradine [48], danazol [49], and salbutamol sulfate [50,51], have been successfully produced by this method.

***8.2.2.3 Flash Nanoprecipitation by Confined Liquid Impinging Jets (CLIJ).*** In this technique, two respective jet streams of a drug solution and an antisolvent are forced together by opposing nozzles that are mounted in a small chamber to create localized, intensified mixing. The mixing causes precipitation of nanoparticles within the residence time of mixing. The velocity, drug concentration, and volume ratio of the two streams are considered to be the factors determining the particle size distribution of a product. CLIJ has been utilized in the production of salbutamol sulfate, ibuprofen, cyclosporin A, and amphotericin B [52–54]. GRAS (generally regarded as safe) additives may be added to assist the production.

***8.2.2.4 Supercritical Fluid (SCF) Technology.*** This method takes advantage of the unique physical properties of supercritical fluids, including low density and viscosity as well as high diffusivity of solute molecules to attain rapid mixing. In addition, quick and easy removal of a SCF without excessive drying can greatly facilitate the precipitation of nanoparticles. Supercritical carbon dioxide ($SCO_2$) is

mostly used and considered green or environmentally friendly for processing most pharmaceuticals. Depending on the solubility of a compound in $SCO_2$, production can be accomplished by allowing the drug–$SCO_2$ mixture to expand under ambient conditions (method called rapid expansion of supercritical solution or RESS [55]) or by using $SCO_2$ as the antisolvent when the drug is poorly soluble in $SCO_2$ (a process is called supercritical antisolvent or SAS [55]). In both the methods, it is critical that other solvents used are miscible with $SCO_2$; water is actually immiscible. Amoxicillin, ampicillin, and rifampicin nanoparticles were successfully produced by the SCF approach [56]. 100–500 nm protein nanoparticles of insulin, rhDNase, lysosome, and albumin were precipitated from aqueous ethanol solution by using ethanol as the co-solvent [57].

***8.2.2.5 Sonoprecipitation.*** Ultrasonic waves can create cavitations that subsequently collapse, releasing shock waves that may assist in rapid and more uniform nucleation [58]. Ultrasound can also reduce particle agglomeration by minimizing particle contacts [43]. Drug microparticles were reportedly produced by the sonocrystallization method [59–61]; it is also shown that the method could produce nanoparticles of amorphous cefuroxime axetil [62]. Factors that influence the quality of a final product include (i) ultrasound frequency, intensity, and power, (ii) sonication probe size and immersion depth, (iii) solution volume, and (iv) duration. Although the experimental setup appears to be straightforward, this technology has not been adopted for commercial production.

The quality of nanocrystals produced by the bottom-up approach is expected to be superior to that by the top-down method. Particle size and morphology can be better controlled, and it is possible to produce pure nanocrystals with little or no amorphous content. Shorter production time, less energy consumption, and reduced contamination also make the precipitation techniques desirable. Clearly, the bottom-up approach holds great promise for developing nanocrystals for parenteral delivery, which demands uncompromised quality and stability. Although no such product is currently in the market, there is certainly a growing interest and need in this field. Challenges remain in controlling nucleation and subsequent crystal growth so that batch-to-batch reproducibility can be achieved. It is certain that among various methods that are being developed, ones that are simple, reproducible, and yet cost-effective for production scale-up should have great potential in commercial production [36].

### 8.2.3 Combined Approach

There have been efforts to combine the two aforementioned approaches. The NanoEdge™ patent by Baxter claims that nanocrystals, ranging from 400 to 2 μm, can be prepared by crystallization followed by high-pressure homogenization [63]. Our research group used an antisolvent approach to grow nanocrystals by rapidly precipitating anticancer drugs under intense stirring and sonication [64,65]. To further reduce the size, the nanocrystal suspension can subsequently be homogenized. Nanocrystals with an average particle size ranging from 200 to 800 nm have

been successfully produced in our laboratory. The second step of homogenization breaks down larger crystals and, particularly, aggregates, achieving a much narrower particle size distribution.

## 8.3 PARTICLE STABILIZATION

Nanocrystals and nanoparticles of drugs, whether prepared by the top-down or bottom-up approach, often require surfactants to be physically attached to the surface of each particle in order to prevent the particles from aggregation during their preparation, storage, and administration. Particle aggregation mutually facilitates Ostwald's ripening and eventually becomes irreversible, leading to larger particles and precipitates. Surfactant usage is particularly necessary when the surface of nanocrystals is uncharged. In general, polymeric surfactants are commonly used to introduce steric repulsion between particles; electrostatic repulsion also promotes particle segregation when ionic surfactants are used. Povidones, pluronics, and cellulosics are the most commonly used surfactants. Natural biological molecules, such as lecithins and cholic acid derivatives, are utilized as well [66].

Finding a suitable surfactant for a particular drug is experimentally demanding [67]. A stabilizer obviously needs to have sufficient affinity for the particle surface and the amount used should provide sufficient steric and/or electrostatic repulsion between the particles [68]. Excess amounts of surfactants do not always lead to better coverage due to the tendency of surfactants to form micelles when the concentration surpasses the critical micelle concentration (CMC) [69,70]. A recent study of the effects of 13 stabilizers during wet milling of 9 drug compounds [71] concluded that the semisynthetic polymers, including hydroxypropylmethylcellulose (HPMC), methylcellulose (MC), hydroxyethylcellulose (HEC), hydroxypropylcellulose (HPC), carboxymethylcellulose sodium salt (NaCMC), and alginic acid sodium salt (NaAlg), yielded rather poor stabilizing performance, likely because of their high viscosity. Less viscous stabilizers, including linear synthetic polymers (PVP K30 and K90) and synthetic copolymers (poloxamer 188 and Kollicoat IR®), showed better stabilizing capabilities, especially at higher concentrations. Tween® 80 and TPGS (D-α-tocopherol polyethylene glycol 1000 succinate) gave the best stabilizing performance. Moreover, the timing of surfactant addition may affect particle properties. Stabilizers are commonly added along with the starting microcrystalline materials for wet milling or homogenization. However, the addition of a stabilizer prior to crystallization may alter the nucleation and subsequent crystal growth outcome. For example, the morphology of the nanocrystals of ZSTK474, a novel PI3K inhibitor [72], that were prepared in our laboratory by the bottom-up approach varied from an elongated to a plate-like shape due to the addition of 1% (w/v) Pluronic® F127 (Figure 8.3).

Because nanocrystals undergo consistent dynamic changes, especially in solution or in contact with moisture—dissolution and surface recrystallization—albeit at a slow rate, surface adsorption by surfactants may not be able to sustain stability of nanocrystals for the long-term storage. Alternatively, nanocrystal products may be

**FIGURE 8.3** SEM images of ZSTK474 nanocrystals grown in the absence (a) and presence (b) of Pluronic F127. Scale bar: 2 μm.

further processed by freeze drying, spray drying, or pelletization [19]; water-soluble sugars, such as mannitol, trehalose, and dextran, are commonly added as matrix formers prior to drying [73]. In the absence of a solvent, the surface dynamics and mobility are greatly minimized. For further sterilization, nanosuspensions for intravenous use are often subjected to terminal heat and gamma irradiation [74] as well as filtration [75], and stored as liquid suspension or lyophilized solid form.

## 8.4 PARTICLE CHARACTERIZATION

### 8.4.1 Particle Size

Nanocrystals need to be fully evaluated to determine their (i) particle size and size distribution, (ii) surface charge, (iii) crystallinity, and (iv) dissolution rate [18,29,73,76]. For rapid and noninvasive determination of the mean particle size and size distribution, photon correlation spectroscopy (PCS) is mostly used for particles ranging from 3 nm to 3 μm. The size distribution is indicated by polydispersity index (PDI), which is indicative of the width of particle size distribution. A PDI value of 0.1–0.25 suggests that the size distribution is fairly narrow, while a PDI value greater than 0.5 indicates a very broad

distribution. To achieve long-term stability, it is important to maintain the PDI parameter as low as possible. When the particle size is >3 μm, laser diffractometry (LD) can be used. Note that the particle size data obtained by LD are volume based, and those by PCS are light intensity weighted. Also note that these techniques work well for spherical particles; for nanocrystals, which tend to have large aspect ratios (i.e., length/width), the size results often deviate significantly from those determined by electron microscope imaging. For nonspherical particles, LD may overestimate the particle size distribution [77,78]. Over-prediction of the median diameters is also observed [79]. Thus, caution is needed when measuring and reporting particle size of irregular shape particles [80]. A coulter counter, which yields the absolute number of particles per volume unit of different size classes, can be used as an additional method, for example, to quantify any contamination from microparticles. When a formulation is intended for intravenous delivery, it is essential to ensure that the particle size is smaller than the smallest blood capillary (a few micrometers) so that potential capillary blockade or emboli formation can be avoided [29].

### 8.4.2 Surface Charge

Surface charging is important for the stability of nanocrystals in solution. According to the Derjaguin, Verwey, Landau, and Overbeek (DLVO) theory, the stability of a colloidal system depends on the balance between two counteracting forces, attractive (van der Waals) and repulsive (electrical double layer) [81]. The electrical double layer surrounding a particle consists of an inner region (Stern layer), where counterions are strongly bound to the particle, and an outer region (diffuse layer), where counterions are loosely associated. Within the diffuse layer, there exists a notional boundary, named the slipping plane, which separates counterions that move along with the particle and those that stay with the bulk fluid. The electric potential difference at the slipping plane versus a point in the bulk medium is defined as the zeta potential. It can be measured by using light scattering to monitor the electrophoretic mobility when the colloidal system is subjected to an electric field. In addition to the sample's surface chemistry, pH of the medium, conductivity of the fluid, and concentration of additives can influence the distributions of counterions surrounding the interface and thereby the zeta potential. To resist flocculation and aggregation, particles need to have sufficiently high repulsion forces. It is generally recognized that a specific value of zeta potential can be useful in predicting the physical stability of a nanosuspension formulation. ±30 mV or larger (absolute value) is desired for an electrostatically stabilized suspension. For particles with smaller zeta potentials, surfactants may be needed to provide further steric and/or electrostatic repulsions [82]. Numerous studies have shown that surface potential can have a drastic influence on cellular uptake or even tumor targeting of nanoparticles [83–87]. One study of cationic and anionic polymeric nanoparticles with similar particle size (90–100 nm) reported that anionic nanoparticles were transited through the degradative lysosomal pathway within the cell, while the cationic particles were transcytosed and accumulated at the basolateral membrane [84]. On the other hand, positively charged micelles caused higher hemolytic activity—due to strong

electrostatic interactions between the particles and the anionic erythrocyte membrane—and accumulated in the liver proportionally to the positive charge density; in contrast, negatively charged micelles were not hemolytic [87]. Highly charged nanoparticles had a much higher opsonization rate than neutral or slightly charged nanoparticles of the same size [87,88].

### 8.4.3 Crystallinity

Crystallinity of a product is often assessed by X-ray diffraction (XRD), complemented by differential scanning calorimetry (DSC). When a compound is known to form hydrates or solvates, thermogravimetric analysis (TGA) is used as well to determine any weight loss at elevated temperature. These analyses also play a key role in characterizing polymorphic forms of a crystalline formulation. In one study to formulate SN 30191, an anticancer drug (PI3K inhibitor), by high-pressure homogenization, the premilled form II particles were converted to form I when the sample was subjected to a pressure between 500 and 1500 bar [89]. Further increase in pressure to 1750 bar resulted in the formation of a hydrate form. Polymorphic transition can considerably change the solubility and dissolution rate, which may alter a compound's *in vivo* performance, such as its bioavailability.

### 8.4.4 Dissolution

Dissolution behavior of nanocrystals can be determined by the USP dissolution apparatus 2 (paddle) or similar methods. A large volume of dissolution medium (e.g., more than 500 mL) may be needed to minimize the influence of withdrawing samples during the measurement. Careful attention is needed when carrying out the solubility measurement of nanocrystals. It is reported that solubility results determined by centrifugation, ultracentrifugation, or filtration may be questionable because of poor separation of solid particles from the solution [90]. In the presence of high-concentration stabilizers or surfactants, solubility of a drug may be apparently increased, likely due to micellar solubilization of the drug [90]. It must be noted that although the dissolution rate of a nanocrystal formulation can be enhanced considerably because of the increase in surface area, solubility increase is minimal. For instance, the solubility of loviride in a nanosuspension was reportedly increased by 15% when the particle size was about 150 nm [90]. For a poorly soluble drug, the absolute increase in the dissolution rate of its nanocrystal formulation is still marginal.

## 8.5 NANOCRYSTALS FOR CANCER THERAPY

Combinatorial chemistry and high throughput screening have promoted a steady increase in the number of drug candidates over the years but the majority have been poorly soluble [91–93]. Among various formulation strategies, reducing the size of solid particles of a drug compound has gained considerable attention as a delivery

method [73]. Although the marketed nanocrystal-based products are mainly for oral delivery, formulated mostly by the top-down approach, nanocrystals have been exploited for other routes as well, including parenteral, dermal, mucosal, ocular, and pulmonary [17]. Relative to the conventional delivery approaches, nanocrystal formulations are free of organic solvents or other solubilizing chemicals, which may cause adverse effects. The administration of escalated doses of nanocrystals, which can be up to 3–10-fold higher than the maximum tolerated dose of a conventional formulation, may result in improved patient tolerability and enhanced therapeutic efficacy [94,95]. More importantly, nanocrystals offer a much stable and well-integrated platform for drug delivery, circumventing many drawbacks associated with the existing delivery designs, such as drug leakage and systemic breakdown during the storage or even administration stage. Such merits become even more desirable for the intravenous delivery of poorly soluble chemotherapeutic agents. The high drug loading and sustained release of drug molecules allow the nanocrystals to fully take advantage of the EPR effect for targeting tumors. To date, the number of studies reported to use nanocrystals for cancer therapy is limited (Table 8.1). Because of the promising values, more studies are expected to emerge. Below, we briefly review some recent studies that characterize the behaviors and performance of nanocrystal formulations of antineoplastic agents *in vitro* and *in vivo*.

Free drug molecules dissolved from nanocrystals enter cells through passive diffusion. Additionally, nanocrystals can be taken up by cells via active transport process, including the clathrin- and caveolae-mediated endocytosis. Particles of a size of 200 nm or less are preferentially internalized by clathrin-coated pits, while particles between 200 and 500 nm are taken up by the caveolae-mediated pathway [96,97]. The maximum size of particles that can internalized through cell membrane is 500 nm [98]. In one of our studies, the addition of chlorpromazine (CPZ), which disrupts clathrin and hence clathrin-mediated endocytosis, reduced the cellular uptake of camptothecin (CPT) nanocrystals by about 20% compared with that of CPT nanocrystals without the inhibitor [64]. Moreover, nanocrystals are often observed to exert greater cytotoxicity than a solution formulation, particularly when the incubation time is relatively short. One study shows that, against PC-3 prostate cancer cells, the $IC_{50}$ value of deacetymycoepoxydiene (DM) nanocrystals was much lower than that of the drug solution after 12 h incubation; the $IC_{50}$ value of the nanosuspension and solution converged when observed at 48 h [99]. Similar observations were made in our laboratory when $IC_{50}$ values of paclitaxel nanocrystals and its solution against the breast cancer cell MDA-MB-231 were compared (not published).

One of the early *in vivo* studies of nanocrystals was conducted in a murine adenocarcinoma model by testing nanocrystals of piposulfan, camptothecin, etoposide, and paclitaxel that were prepared by ball milling [94]. Solubility values of these drugs range from 200 to $<4$ μg/ml. It was found that, when given intravenously using a multiple-dose regimen at the maximum tolerated dose (MTD), the nanocrystal formulations of the four chemotherapeutic drugs were able to suppress the tumor burden with no death reported, while control formulations using organic solvents and surfactants to solubilize the drugs caused 20% or more mortality. The significant

**TABLE 8.1 Nanocrystal Formulations of Anticancer Drugs**

| Compound | Method | Stabilizer(s) | Average Size (nm) | Zeta Potential (mV) | Reference |
|---|---|---|---|---|---|
| Piposulfan | MM | Tween 80, Span80 | 210.2 ± 38.9 | N/A | [94] |
| Camptothecin | MM | Pluronic F108 | 202.3 ± 30.5 | N/A | [94] |
| Etoposide | MM | Pluronic F127 | 256.2 ± 53.0 | N/A | [94] |
| Paclitaxel | MM | Pluronic F127 | 279.2 ± 29.60 | N/A | [94] |
| Asulacrine | HPH | Poloxamer 188 (Pluronic F68) | 702 ± 0.02(d90) | N/A | [105] |
| SN30191 | HPH | Poloxamer 407, Solutol HS15, Mannitol | 1200–1300 (d90) | N/A | [89] |
| Paclitaxel | 3PNET | Pluronic F127 | 122 ± 35 | 0.82 | [95,118] |
| Oridonin | HPH | Pluronic F68, lecithin, HPMC, PVP | 322.7; 103.3 ± 1.5 and 897.2 ± 14.2; 912.5 ± 17.6 | −26.74 ± 2.68; −20.3 ± 0.4, −21.8 ± 0.8; N/A | [70,106,119] |
| DeacetyMycoepoxydiene | HPH | Lecithin, Pluronic F68, HPMC, PVP | 423 ± 11 | −23.1 ± 3.5 | [99] |
| Quercetin | HPH, EPAS | Pluronic F68, Lecithin | 213.6 ± 29.3 (HPH); 282.6 ± 0.02 (EPAS) | −22.48 ± 4.6 (HPH); −21.12 ± 2.7 (EPAS) | [120] |
| Paclitaxel | SLbL, US | Polyelectrolytes, BSA | 100 ± 20 nm (SLbL); 220 ± 20 (US) | −45 ± 3 | [121] |
| Camptothecin | Anti-solvent | Without stabilizer | 234.4 ± 35.6 | −41.8 ± 1.3 | [64] |
| Paclitaxel | Anti-solvent | Without stabilizer | 438.5 ± 8.3 | −15–22 | [65] |

HPH, high pressure homogenization; MM, media milling; EPAS, evaporative precipitation into aqueous solution; 3PNET, three-phase nanoparticle engineering technology; SLbL, sonication assisted layer-by-layer polyelectrolyte coating; US, ultrasonication.

increase in the MTD of nanocrystals is also reported by a recent study in which paclitaxel nanocrystals were formulated by a three-phase nanoparticle engineering technique and tested in two murine tumor models [95]. The nanocrystals were given at a dose equivalent to the MTD of a Cremophor-EL solubilized dosage form (20 mg/kg), and both formulations showed similar treatment efficacy. The nanocrystals showed much improved therapeutic outcome when administered at 60 mg/kg. The PTX nanosuspensions were also tested by oral administration but found to be less effective than the parenteral dosage form.

Intravenously administered nanocrystals are expected to reach tumors via the EPR effect. We found that camptothecin nanocrystals, administered in a MCF-7 xenografted murine tumor model, yielded significantly better antitumor activity ($p < 0.01$) than the drug salt solution [64]. Biodistribution results at 24 h after the injection further revealed that CPT nanocrystals accumulated in the tumor at a much higher level than the salt solution. Note that a majority of nanocrystals (or any nanoparticle drug delivery systems) are still being taken up by the reticuloendothelial system (RES), mainly liver and spleen [100]. A common practice to reduce the RES uptake and enhance biocompatibility is to modify the surface of a nanosystem is commonly modified, physically or chemically, with biocompatible polymers, such as polyethylene glycol (PEG), that is known to prolong the systemic circulation [101]. Because nanocrystals continue to dissolve after their administration, surface coating by polymeric surfactants onto the nanocrystals may not work. Thus, there is a critical need to investigate new ways to incorporate biocompatible molecules (and other functional molecules) to nanocrystals. Nonetheless, relative to solution-based delivery systems, nanocrystals are expected to accumulate in the tumor by at least an order of magnitude more (from less than one to a few percent) at the same dose level. Given the stable integrity, nanocrystals hold a great promise in targeted cancer therapy.

The particle size of a nanoparticle delivery system has a fundamental influence on the pharmacokinetics (PK) and biodistribution of the nanoparticles. It has been suggested that particles between 50 and 300 nm can achieve prolonged blood circulation [100,102], which helps their accumulation in solid tumors via the EPR effect [100,103,104]. With the same surface charge of −25 mV, polymeric nanoparticles with the size of 150 nm were reported to have significantly longer circulation time due to the low uptake by the RES than particles of 500 nm [85]. Compared with a solution formulation, optimally designed nanovehicles are expected to bear improved PK behaviors, including increased half-life ($t_{½}$), reduced clearance (Cl), increased area under the curve (AUC), and increased mean residence time (MRT) [104]. The PK of intravenously injected nanocrystals of chemotherapeutics (e.g., paclitaxel, asulacrine, and oridonin) was reported to be quite distinctive, best described by a two-compartmental model, where the elimination was nonzero order [105–107]. In a rabbit model, the pharmacokinetic profile of 103 nm oridonin nanocrystals, which were shown to dissolve rapidly, was similar to that of the drug solution [70]. On the contrary, the 300 nm paclitaxel [107] and 700 nm asulacrine nanocrystals [105] were rapidly taken up by the RES organs, such as liver, spleen, and lungs, resulting in shortened distribution half-lives ($t_{½}\alpha$) and decreased AUC. The decreased and yet prolonged AUC in plasma was found to be beneficial to

minimize the toxic drug exposure. Interestingly, the 900 nm oridonin nanocrystals were found to achieve decreased Cl and $t_{1/2}\alpha$ and increased AUC as compared with the dissolved drug [70]. Overall, prolonged elimination half-life ($t_{1/2}\beta$) and MRT were observed for nanocrystals between 300 and 900 nm [105–107]. The sustained blood concentrations likely resulted from slow release of drug molecules from nanocrystals trapped by the RES organs [105,106]. Size has also been found to affect particle accumulation and retention in the tumor. Small particles may accumulate faster in tumors, but larger ones can be retained longer [108]. Moreover, particle accumulation in the tumor relies on the leakiness of the tumor vasculature, which is further determined by the tumor type [109,110], histological grade, and malignant severity [111]. The cutoff sizes of pores in the tumor vasculature range from 200 nm to as large as 1.2 μm, with the majority between 380 and 780 nm [110]. Collectively, it has been suggested that in order to take advantage of the EPR effect and target tumors, nanoparticles should be smaller than 400 nm [108]. The particle size is nonetheless one of many factors that determine the pharmacokinetics and biodistribution of nanoparticles. Surface chemistry plays an important role as well. Because their surface is decorated with hydroxyl groups, amorphous silica particles with sizes of 50 and 250 nm, respectively, exhibited significantly higher blood to liver ratios compared with 180 nm PEG-coated solid lipid nanoparticles in a Wistar rat model [102]. Despite their intrinsic hydrophilicity, which resulted in decreased RES clearance, detailed toxicological studies of amorphous silica particles are still limited [112].

A recent clinical study of Panzem®, a nanocrystal dispersion of 2-methoxyestradiol (2ME2), an endogenous estradiol-17β metabolite that bears antimitotic and antioangiogenic activities, demonstrated an improved pharmacokinetic performance and antitumor activity relative to its capsule formulation when given orally to 16 patients with advanced solid malignancies and 14 patients with taxane-refractory, metastatic castrate-resistant prostate cancer [113,114]. Despite the fact that the 2ME2 nanocrystal formulation was well-tolerated and showed evidence of biologic activity, it did not appear to have sufficient clinical activity and the study was terminated at phase II. No other clinical studies to test parenteral nanocrystal formulations for cancer therapy have been reported.

## 8.6 FUTURE PERSPECTIVES

Nanocrystals have shown promising potentials for drug delivery, particularly for delivering poorly water-soluble anticancer drugs. Major challenges still remain and must be overcome before nanocrystal-based formulation can be fully embraced for treating patients. One such difficulty is production of high-quality nanocrystals with a uniform particle size and morphology. These properties are especially desired for parenteral dosage forms. The top-down approach lacks a well-defined mechanism to control the particle size; the high-energy process may damage the crystallinity of fragmented particles, which presents a concern for the physical stability of a final product. On the other hand, the bottom-up approach stems from solution

crystallization, which has been extensively investigated over decades with regard to mechanism and kinetics. The broad understanding will eventually lead to technical breakthroughs in controlling the particle size, size distribution, and shape of nanocrystals produced from solution. More studies nevertheless remain to be done, particularly for fine-tuning the nucleation process at the industrial scale to ensure uniformity and reproducibility.

Another challenge of using nanocrystals for cancer therapy is seemingly a lack of feasible means to enhance biocompatibility and improve cancer targeting. Tumor-targeting moieties to augment cellular uptake cannot be chemically attached to the crystal surface. Physical adsorption directly or conjugated with surface-coated surfactants may not be suitable either because of continuous dissolution of nanocrystals. Also because of the dynamic nature of dissolution, any surfactants used to prevent nanocrystals from agglomeration and/or to enhance systemic circulation can be easily detached from the nanocrystal surface during blood circulation and extravasation. These limitations seem to drastically dampen the application of nanocrystals for cancer therapy. Similarly, it seems to be difficult, if not impossible, to develop theranostic nanocrystal systems that integrate imaging or diagnostic agents with a drug substance.

So comes the hybrid nanocrystal concept. Over the last few years, our laboratory has developed nanosized hybrid crystals, through which a functional material is physically integrated. The concept was inspired by a well-known phenomenon in solid-state chemistry wherein impurities are entrapped in the crystal lattice of a host particle. The existence of foreign substances in a host is typically insignificant, having little effect on the structure and integrity of the host crystal structure but capable of casting drastic influence on the optical appearance and other physical properties of the host. Examples are abundant. Colored diamonds are one famous example; synthetic hybrid crystals include alloys and semiconductors. The most relevant examples are dyeing crystals, where guest dye molecules are integrated in organic crystals [115]. Hybrid nanocrystals of paclitaxel were developed in our laboratory to integrate fluorescent probes and tested in a murine tumor model [65]. The results indicated that the nanocrystals were capable of not only exerting antitumor effect but permitting real-time imaging of the delivery system in animals. Figure 8.4 shows the hybrid paclitaxel nanocrystals and

**FIGURE 8.4** SEM image of paclitaxel/fluorophore (FPR-749) nanocrystals (a, scale bar: 2 μm), and fluorescence images obtained by IVIS of two mice bearing MCF-7 xenograft tumors in rear flanks. FPR-749 solution (left) and the hybrid nanocrystals (right) were intravenously injected via tail vein and images were captured at 25 min (b), 4 h (c) and 48 h (d), respectively. Exposure time was 0.25 s, F-stop 2, and binning medium.

whole-body fluorescence images of mice intravenously injected with either dissolved or integrated fluorophore. We are currently expanding the concept to integrate other types of functional compounds, including radioisotopes, ligands, and polymers. Because the guest substance is integrated within a nanocrystal host, hybrid nanocrystals are expected to advance the usage of nanocrystals for cancer therapy.

Finally, although the focus of this chapter is organic nanocrystals, we cannot discount the development and application of inorganic nanocrystals in drug delivery and cancer treatment. Quantum dots (QDs) have been widely used in cellular imaging [116,117]. Other inorganic nanosystems, including iron oxide, silica, gold, and even carbon nanotubes have been explored as drug delivery systems.

# CLEARANCE OF NANOPARTICLES DURING CIRCULATION

Seung-Young Lee and Ji-Xin Cheng
*Weldon School of Biomedical Engineering, Purdue University, West Lafayette, IN, USA*

## 9.1 INTRODUCTION

Administration of conventional therapeutic agents for cancer therapy is often limited due to their chemical properties, such as low solubility and poor stability in blood. These properties cause a short circulation half-life and low therapeutic efficacy, thus necessitating frequent administrations. In addition, toxic side effects of these agents due to nonspecific biodistribution have been additional issues in cancer chemotherapy. To overcome the limitations of conventional therapeutic agents, researchers have explored drug delivery systems that can safely and efficiently carry drugs and deliver them to the tumor site without affecting normal tissues [1–3]. In this regard, nanoparticle systems have gained a lot of interest because of the drug loading capacity and the ability to easily pass through anatomical barriers. Delivery of nanoparticles to solid tumors is facilitated by the leakiness of tumor blood vessels [4,5], and the discovery of various tumor-specific ligands has enabled more efficient delivery of nanoparticles to cancer cells [6,7].

One of the key factors to determine the targeting efficacy of nanoparticles is their blood-circulation time because long-circulating nanoparticles have more chances to transport into tumor tissues [8,9]. The circulation half-life of the nanoparticles primarily depends on the rate of the biological clearance [10,11]. The clearance mechanisms can be classified into three categories: (i) disintegration of nanoparticles by protein adsorption, (ii) opsonization-mediated nanoparticle removal by immune

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*,
Edited by Shayne C. Gad

cells, and (iii) filtration by organs with fenestrated vasculature. Biological clearance of nanoparticles is influenced by physiochemical properties of the nanoparticles, such as surface charge, composition, size, shape, and deformability [12–14]. To extend the circulation time of nanoparticles in the blood stream, nanoparticles are modified in various ways.

## 9.2 NANOPARTICLE-BASED DRUG CARRIERS IN CANCER THERAPY

### 9.2.1 Nanoparticle-Based Drug Carriers

Nanoparticles with a size ranging from 1 to 1000 nm have been considered promising drug carriers. Their distinct advantages include flexible control of particle size and surface properties, the compatibility with various routes of administration (e.g., topical, enteral, and parenteral), and the ability to protect anticancer drugs against clearance in the blood and to provide controlled drug release such as sustained or pulsatile drug release [15–18].

Nanoparticle-based drug carriers were first introduced in 1950–1960s as liposomes and polymer–drug conjugates [19,20]. Since then, various nanoparticle-based drug carriers have been developed for the enhancement of chemotherapy [21,22]. In particular, advancement in nanotechnology and biomaterials has contributed to the improvement of existing nanoparticle systems and the development of new drug delivery systems (Table 9.1) [11,23–43]. These nanoparticle-based drug carriers help enhance drug localization in tumor tissues and reduce cytotoxicity for normal tissues compared to free drug.

### 9.2.2 Tumor Targeting Strategies

An ideal nanoparticle-based drug carrier for chemotherapy should first guide a drug to the targeted tumor tissues while preserving therapeutic activity of the drug during circulation. Secondly, after reaching tumor tissues, nanoparticles should release the drug to kill tumor tissues selectively and site specifically, reducing collateral damages to normal tissues [44–46]. Currently, passive and active tumor targeting strategies are used to deliver nanoparticles to the tumor sites.

***9.2.2.1 Passive Tumor Targeting.*** Most solid tumors possess leaky vasculature induced by vascular permeability factors such as bradykinin, nitric oxide (NO), peroxynitrite ($ONOO^-$), prostaglandins, vascular endothelial growth factor (VEGF), matrix metalloproteinases (MMPs), kallikrein, and tumor necrosis factor (TNF) [4,47]. High concentrations of these secreted factors around tumor tissues accelerate the formation of new blood vessels (neovascularization or angiogenesis) to supply oxygen and nutrients for tumor growth. This results in hyperpermeable vasculature, which allows macromolecules or nanoparticles to access tumor tissue. In addition, many solid tumors are known to develop a defective lymphatic drainage system, causing the molecules and nanoparticles to be retained there [48]. The cut-off size of

**TABLE 9.1 Nanoparticle-Based Drug Delivery Systems**

gap junctions between endothelial cells in permeable tumor blood vessels is around 200–800 nm [5], which enables accumulation of nanoparticles having the similar size. This phenomenon is known as the enhanced permeability and retention (EPR) effect, a critical principle for the passive tumor targeting of nanoparticles [49]. After accumulation in the tumor tissues, the drug is released into extracellular matrices, where it diffuses into intracellular sites.

Most nanoparticle-based drug carriers rely entirely on this EPR mechanism to facilitate delivery to the tumor. Despite a wealth of documentations on the EPR effect, tumor targeting efficacy through the EPR effect remains controversial. This controversy stems from the fact that there is no major driving force facilitating the passive extravasation of nanoparticles through the leaky vasculature [50]. It is currently believed that passive nanoparticle extravasation via the EPR effect occurs by diffusion and convection in blood flow. However, these forces actually play a minor role in the transport of nanoparticles to the interstitium of tumors compared to bulk fluid flow [51]. Interstitial fluid pressure in tumor is higher than intravascular pressure due to the defective lymphatic drainage [52]. Furthermore, blood pressure in solid tumors tends to increase toward the tumor center, which drives overall mass transport of fluid away from the center [53,54]. As a result, nanoparticle transport to central tumor regions is remarkably limited. A recent report describes that this problem was experimentally addressed by increasing systemic blood pressure with angiotensin II (AT-II) [55] or facilitating tumor blood flow using nitroglycerin (NG) [56]. This approach resulted in temporary augmentation of the EPR effect and drug delivery to tumor tissues [57].

***9.2.2.2 Active Tumor Targeting.*** Another strategy for tumor targeted drug delivery is active targeting using tumor-binding ligands [58,59]. Here nanoparticles are decorated with a ligand as a targeting moiety on the surface, which helps their entry into the cells. Cellular internalization of these nanoparticles occurs via receptor-mediated endocytosis [60,61] and is especially important in biotherapeutic delivery such as DNA and small interfering RNA (siRNA) [62]. Various targeting ligands for cancer therapy, such as RGD peptides for targeting $\alpha_v\beta_3$ integrins in tumor vasculature and folic acid for targeting folate receptors on cancer cells, have been identified and used for targeted drug delivery (Table 9.2) [63–71]. However, the mechanism of active targeting nanoparticles is not entirely clear [72], and the effectiveness of ligands remains controversial. Several recent reports have shown only a modest improvement in tumor accumulation of the ligand-decorated nanoparticles compared to nanoparticles with no ligands [73,74]. The results of these studies suggest that the tumor localization of nanoparticles is independent of the ligand and primarily relies on the EPR effect.

## 9.3 BIOLOGICAL CLEARANCE OF NANOPARTICLES

When the nanoparticle delivery to tumor tissues largely depends on the EPR effect, circulation time of nanoparticles in the blood is one of the most important properties [8]. The long circulation time provides nanoparticles with a great opportunity to transport

**TABLE 9.2 Tumor Molecules and Ligands for Active Targeting**

| Target Site | Target Molecule (or Receptor) | Ligand | Reference |
|---|---|---|---|
| Tumor vascular targeting | VEGF receptor | CBO-P11 | [63] |

into tumor tissues through the leaky vasculature and interact with target receptors on tumor cells [75]. The circulation time of the nanoparticles in the blood is determined by the rate of biological clearance from the blood, spleen, liver, and kidney (Figure 9.1) [10,76]. While biological clearance is a natural protection mechanism against invasion by foreign organisms, it is a significant obstacle for the application of nanoparticles in cancer therapy. In addition, the localization of drugs or nanoparticles in filtering organs such as the liver and the spleen can cause hypersensitivity reactions such as exaggerated immune responses, making the concept of targeted drug delivery to eliminate secondary toxicity pointless [77–80]. To evade rapid biological clearance, various approaches have been developed focusing on surface modification or controlling the physiochemical properties (size, shape, surface charge, and deformability) of nanoparticles, which play critical roles in their biological clearance [81–84].

### 9.3.1 Blood Clearance

***9.3.1.1 Protein Adsorption and Opsonization.*** Plasma proteins immediately cover the surface of administered nanoparticles, which they recognize as foreign materials [85,86]. Mechanisms of plasma protein binding to nanoparticles are not yet fully understood due to the complexity of the binding events between the proteins and nanoparticles. Proteins associated with various nanoparticles have been determined by protein separation and identification techniques such as centrifugation, gel filtration, two-dimensional polyacrylamide gel electrophoresis (2D-PAGE), and atomic force microscopy [87–89]. The composition of proteins adsorbed to the nanoparticles primarily depends on the protein concentration, kinetics of protein binding, and surface characteristics of the nanoparticles (Table 9.3) [90–104]. Abundant plasma proteins such as albumin, immunoglobulin G (IgG), fibrinogen, and apolipoproteins are first adsorbed on most types of nanoparticles. Over time, these proteins are sequentially exchanged with other

**FIGURE 9.1** Biological clearance of nanoparticles in blood circulation, liver, spleen, and kidneys. (*Source:* Modified from Reference [10].)

high affinity proteins. The exchange rates are relative to the chemical properties and stability of the protein [105]. For instance, fibrinogen binds immediately onto the surface of solid lipid nanoparticles and is rapidly displaced by apolipoproteins after 0.5 min incubation in blood [106]. Protein binding to iron oxide particles also changes with the plasma concentration and incubation time [107].

Physiochemical properties of nanoparticles that influence protein adsorption to their surface include surface charge, hydrophobicity, particle size, surface curvature, and surface area. Electrically neutral nanoparticles have distinctly less protein adsorption than charged nanoparticles [108–110], whereas protein adsorption increases in general for negatively charged nanoparticles [111]. The composition of adsorbed proteins depends on the functional groups and its charge. For example, proteins with an isoelectric point below 5.5 (e.g., albumin) have affinity for positively charged nanoparticles with amine groups ($–NH_2$), while those with isoelectric point above 5.5 (e.g., IgG) was shown to be predominantly adsorbed to negatively charged nanoparticles with carboxyl acid (–COOH) [112]. Macrophage uptake of positively charged nanoparticles was greatly increased by albumin adsorption [113]. Hydrophobicity of a nanoparticle surface is another key factor

**TABLE 9.3 Nanoparticle Systems and Opsonins**

| System | Identified Oposnins | Reference |

in plasma protein adsorption [108]. Higher hydrophobicity of the nanoparticle surface resulted in greater and faster protein binding [114–116]. The effects of size, surface curvature, and surface area of the nanoparticles on protein adsorption have also been evaluated. A study using *N*-isopropylacrylamide (NIPAM) and *N*-*tert*-butylacrylamide (BAM) copolymer nanoparticles with sizes ranging from 70 to 700 nm found the same amount of protein adsorption [117]. In contrast, another study on poly methoxypolyethyleneglycol cyanoacrylate-*co*-*n*-hexadecyl cyanoacrylate (mPEG–PHDCA) copolymer nanoparticles with three different sizes (80, 170, and 240 nm) demonstrated that larger nanoparticles had greater amounts of protein binding. The amount of proteins adsorbed to nanoparticles with a particle

size of 80, 170, and 240 nm was 6, 23, and 34% of serum protein, respectively [118]. These conflicting results may be ascribed to the difference in material systems. Alternatively, change in one property of nanoparticles may have been accompanied by inadvertent change in other properties, which can influence the protein adsorption profile.

***9.3.1.2 Disintegration of Nanoparticles by Protein Adsorption.*** Protein adsorption can trigger the disintegration of nanoparticles, compromising their function as drug carriers. The instability of polymeric micelles by plasma protein binding has been investigated [119]. The disintegration of poly(ethylene glycol)–poly(caprolactone) (PEG–PCL) micelles in serum solution was shown using fluorescence self-quenching method [120]. *In vitro* and *in vivo* disintegration of poly(ethylene glycol)–poly(DL-lactic acid) (PEG–PDLLA) micelles by α- and β-globulins was also shown using the fluorescence resonance energy transfer (FRET) technique [121,122]. There are three possible mechanisms associated with the disintegration of micelles by plasma protein: protein adsorption, protein penetration, and drug extraction by proteins (Figure 9.2) [123]. Unstable nanoparticles may be quickly eliminated in systemic circulation by protein-mediated disintegration [121].

***9.3.1.3 Opsonization-Mediated Nanoparticle Uptake by Immune Cells.*** Another main clearance pathway of nanoparticles is the uptake of nanoparticles by immune

**FIGURE 9.2** Disintegration of nanoparticles by plasma protein; protein adsorption, protein penetration, and drug extraction by proteins (*Source:* Modified from Reference [123].)

cells. Immune cells both in the blood stream (leukocytes, monocytes, platelets, and dendritic cells) and in organs (Kupffer cells in liver, macrophage and B cells in spleen, and dendritic cells in lymph nodes) engulf and remove the nanoparticles from the blood circulation. This process is generally mediated by binding of specific receptor proteins called opsonins to the surface of nanoparticles [124]. The bound opsonins, such as plasma proteins, immunoglobulins, and component factors in complement system, facilitate the nanoparticle uptake into immune cells, negatively affecting the biodistribution of nanoparticles and hence drug delivery to target tumor tissues [125,126]. The opsonins on the nanoparticle undergo conformational changes and are recognized by the immune cells via specialized receptors [108].

Macrophages are mainly responsible for the clearance of large molecules like nanoparticles. The receptor-mediated phagocytic pathways are classified into four categories (mannose receptor-, complement receptor-, immunoglobulin Fcγ receptor-, and scavenger receptor- mediated phagocytosis) according to the opsonins adsorbed onto the nanoparticles [124]. Through these mechanisms, opsonins such as IgG, apolipoproteins, and fibrinogen promote phagocytosis of nanoparticles by macrophages in the reticuloendothelial system (RES) [106,107,127]. These nanoparticles are subject to localization in RES organs such as the liver and spleen, and eventually eliminated by resident immune cells [113,128,129]. Adsorption of fetuin and fibronectin triggers the phagocytosis of polystyrene nanoparticles by Kupffer cells via the scavenger receptor [130,131]. Increasing the amount of C3 and IgG adsorbed on lecithin-coated polystyrene nanoparticles caused an increased uptake of Kupffer cells [132]. Preopsonization of poloxamine-coated polystyrene nanoparticles by incubation in serum solution accelerated the phagocytosis by macrophages [133,134]. Furthermore, during the clearance process, immune cells produce proinflammatory responses, which involve the secretion of cytokines such as tumor necrosis factor-α, interleuckin-12, and interferon-γ. These cytokines recruit more immune cells to take up nanoparticles. This can cause immunotoxicity and severe damages to the RES organs [77]. However, the effect of nanoparticle opsonization is not always destructive. Some studies have shown that opsonins can enhance tumor targeting and blood circulation time of nanoparticles. For example, dysopsonins, such as albumin, extended the retention time of nanoparticles in the blood [135,136]. In addition, various apolipoproteins enabled nanoparticles to transport across the blood–brain barrier (BBB) for brain tumor therapy [137].

### 9.3.2 Organ Filtrations

Some organs and tissues have naturally permeable vasculature in order to conduct their physiological functions. The inherent gaps between endothelial cells in vessels of those organs, called fenestration (Figure 9.3) [138], play a major role in determining the biological fate of nanoparticles.

While the fenestration of nanoparticles can be used for tumor targeting similar to the EPR effect, it can also cause rapid clearance and nontargeting effect of

**FIGURE 9.3** Schematic illustration of vascular extravasations of nanoparticles in either continuous or fenestrated tissues.

nanoparticles. The size and structure of a fenestration depend on the physiological functions of the organs and tissues (Table 9.4) [5,47,139–150]. Furthermore, the size of a fenestration can change under various pathological conditions [151]. In the spleen, nanoparticles should pass through splenic fenestrations (splenic sinuses) to remain in blood circulation, while, in the liver, the nanoparticles should avoid going through hepatic fenestrations (hepatic sinuses). Otherwise, nanoparticles may be captured by the hepatocyte tissues (hepatocytes cluster), where the nanoparticles are eliminated by Kupffer cells and hepatocytes. Therefore, to improve the blood circulation and tumor targeting of nanoparticles, an understanding of anatomical fenestrations is essential [138]. Of many organs and tissues that contain

**TABLE 9.4 Sizes of Fenestration in Different Organs and Tissues**

| Organ or Tissue | Fenestration Size | Animal Model | Reference |
|---|---|---|---|
| Spleen | 150 nm | Mice | [139,140] |

fenestrations, we focus on the organs mainly responsible for the clearance of nanoparticles, such as spleen, liver, and kidneys.

***9.3.2.1 Spleen.*** The main function of the spleen is to filter the blood [152,153]. The spleen possesses tree-shaped branching arterial vessels that are linked to a venous sinusoidal system (Figure 9.4a) [154,155]. The frame of the spleen is mainly composed of fibrous connective tissue called trabecula. The smaller arterial vessels are surrounded by the lymphoid tissues, which form the white pulp of the spleen. Some of the smallest arterial branches end in the marginal sinus located between the white pulp and the marginal zone, while other branches cross the marginal zone to form the venous system of the red pulp, where mechanical blood filtration occurs [154]. To efficiently filter antigens, microorganisms, and old red blood cells (erythrocytes) from the blood, the venous system of the red pulp has a unique microanatomical structure. Arterial vessels eventually reach into cords in the red pulp, where they are structured as an open blood system without an endothelial barrier [156]. A large number of splenic macrophages are resident in the cords to remove unfiltered organisms. After the blood is purified in the venous sinuses of the red pulp, it is collected in the efferent veins, and finally leaves the spleen through the collecting veins.

To transport through the venous sinuses, red blood cells must pass through the sinus wall. The sinus wall consists of a lining of endothelial cells with basement membrane (stress fiber) and filamentous bands (annular fiber). The rod-shaped endothelial cells are positioned in parallel to the longitudinal axis of the sinus and connect to each other by the stress fiber running along the cellular axis. The annular fiber composed of extracellular matrix components connects to the

basement membrane along the interendothelial slits and forms the endothelial cells into tubular pattern (Figure 9.4b) [157,158]. The unique arrangement of the endothelial cells lining the sinus wall forces the blood to pass through the slits to travel from the cords into the sinus [155]. The slits seldom exceed 0.2–0.5 μm in width [157]. However, these narrow slits do not hinder the passage of healthy red blood cells, whose diameters range from 6 to 8 μm, because of their high degree of deformability, whereas unhealthy blood cells having rigid membranes get stuck in these slits and are ultimately eliminated by the splenic macrophages in the cords (Figure 9.4c) [155]. Large and stiff nanoparticles when injected into the blood stream can also be removed by the same splenic filtration process. Although the recognition of pathogens by macrophages occurs via specific opsonin receptors as discussed earlier, the physical filtration system of the spleen potentially helps splenic macrophages to recognize pathogens stuck in sinus slits [152]. Therefore, physiochemical properties of nanoparticles such as size, flexibility, shape, and surface properties influence passage across the sinus slits in the spleen. It has been reported that splenic clearance of polystyrene nanoparticles increased with their size [159,160]. Also, rigid chitosan nanoparticles with the highest degree of substitution (DS) of 5β-cholanic acid showed rapid accumulation in the mouse spleen via the filtration mechanism, compared to softer chitosan nanoparticles with low DS of 5β-cholanic acid [11]. These studies indicate that the physical properties of nanoparticles such as size and deformability play a pivotal role in splenic passage.

***9.3.2.2 Liver.*** The liver has multiple functions including metabolic control, nutrient (e.g., glycogen) storage, plasma protein synthesis, hormone production, and the elimination of foreign or toxic substances (detoxification) [161]. Here, we focus on the detoxification process in the liver that directly relates to the clearance of nanoparticles. The liver receives blood from both the hepatic portal vein and the hepatic arteries. Around 75% of the liver's blood supply is obtained through the hepatic portal vein that drains the blood from the small intestine, stomach, spleen, and pancreas. The remaining 25% of the blood supply comes from the hepatic arteries. The hepatic portal vein and the hepatic arteries branch out in the liver and are combined at the entrance to the hepatic sinusoids [161]. The blood then passes through the sinusoids and collects in the central vein that drains into the hepatic vein (Figure 9.5a) [162].

The basic functional unit of the liver is the hepatic lobule (Figure 9.5b), which consists of a concentric arrangement of hepatocytes (hepatic cords) radiating outward from the central vein and those separated by the sinusoids. The portal triads include a bile duct, the terminal branches of the hepatic artery, and portal vein, which are regularly located at the vertices of the lobule. The sinusoids are lined by fenestrated endothelial cells and have no recognizable basement membrane. These unique fenestrations allow hepatocytes to have direct exposure to the blood in the space of Disse. The space of Disse generally contains extracellular matrix proteins (e.g., reticular fibers), fibroblasts (e.g., hepatic stellate cells), and dendritic cells. Hepatic macrophages (Kupffer cells) reside in the sinusoidal endothelium [162].

**FIGURE 9.5** Structure of a liver lobule. (a) Schema of the liver lobule, (b) sinusoid in the liver lobule (*Source:* Modified from Reference [162]), (c) scanning electron micrograph (SEM) of the sinusoid (*Source:* Professor Robin Fraser, University of Otago, New Zealand; reproduced per the copyright release to the public domain).

During the detoxification process, Kupffer cells exclusively phagocytose large particles (e.g., 800 nm in diameter), whereas hepatocytes mainly endocytose small particles (e.g., 50 nm in diameter) transported through the endothelial fenestrations [163,164]. Particles taken up by hepatocytes are excreted through the bile by biliary excretion [165]. The size of the fenestration for rats is reported to be around 100 nm in mean diameter under physiological conditions, and the fenestrations are clustered in groups of 10–100 fenestration occupying 2–20% of the sinusoidal endothelial cell surfaces (Figure 9.5c) [142,166,167]. These fenestrations provide a sieving function of sinusoidal blood. Since the liver is a key organ that stores nutrients and removes toxic substances, the internal blood flow rate in the liver is quite slow. This enhances the absorption of plasma nutrients and foreign organisms by the hepatocytes inside the fenestration [161].

This mechanism also contributes to the clearance of small nanoparticles that can pass through the hepatic fenestrations. Most small sized nanoparticles (<100 nm in diameter) have shown substantial accumulation in the liver. Examples are shell cross-linked PEG–poly(*t*-butyl acrylate) nanoparticles (18–37 nm in diameter) [168], DNA–PEI complex with crystallized ligand shell (<50 nm in diameter) [169], PEGylated iron oxide (SPIO) (6.2 nm in average diameter) [170], cyclodextrin–camptothecin nanoparticles (30–40 nm in diameter) [171], core cross-linked *N*-isopropylacrylamide (NIPAm) nanoparticles (around 50 nm in diameter) [172], and quantum dots (3.4–5.5 nm in diameter) [173]. Hepatotoxicity testing

of silica nanoparticles with different sizes (70, 300, and 1000 nm in diameter) found that only the small nanoparticles (70 nm) caused hepatic toxicity [174]. Another study on the biodistribution of PEGylated polystyrene nanoparticles (50 and 140 nm in diameter) in mice demonstrated that most small nanoparticles were found in the cytoplasm of hepatocytes after 24 h post injection, whereas relatively large nanoparticles mainly internalized into Kupffer cells [175]. Recently, a study exhibited silica nanoparticles (~20 nm in diameter) were excreted through the fecal matter (via the liver and the bile), indicating that these nanoparticles had passed through the hepatic fenestrations and endocytosized by hepatocytes [176]. It is therefore evident that relatively small nanoparticles tend to be mechanically trapped in the liver through the sinusoidal fenestrations and preferentially removed by hepatocytes rather than Kupffer cells located on the sinusoidal endothelium [177].

***9.3.2.3 Kidneys.*** The kidneys play major role in homeostasis by maintaining the purity and constancy of internal fluids in the body. The unique filtration system of the kidneys allows wastes and excess ions to be excreted by urine, while essential substances are reabsorbed to the blood [161]. The kidneys cleanse approximately one-quarter of total blood supply in the body each minute. The blood enters the kidneys through the renal artery, which divides into several branches called interlobar arteries. Then, at the medulla-cortex border, the interlobar arteries branch into the arcuate arteries, which curve over the medullary pyramids. Smaller interlobar arteries branch off the arcuate arteries, which supply the cortex at the outer region of the kidneys. Once cleansed, the venous blood collects and leaves the kidneys through the renal vein [161]. Nephrons are the basic functional units of the kidneys responsible for eliminating toxins, wastes, and foreign materials from the body via urine. Each nephron consists of two main structures: a glomerulus and a renal tubule (Figure 9.6) [161]. The closed end of the renal tubule is cup-shaped and completely covers the glomerulus, which is called the Bowman's capsule. Entangled podocytes in the glomerulus form porous membranes called filtration slits. This slits allow small wastes to transport from the plasma to the renal tubule.

The renal filtration is a nonselective, passive, and mechanical process. Thus, glomerular filtration of an object is highly dependent on its size. The filtrate follows the renal tubule, reaches the bladder, and is eventually excreted as urine. Useful substances in the filtrates are reabsorbed by the tubule. The size of the renal filtration slits in rats is around 39 nm [179]. However, the actual slit size is about 4.5–5 nm due to the stratified nature of the glomerular capillary walls [143]. The filtration size threshold of PAMMA dendrimer for mice has been reported to be around 5.4 nm [180,181]. While quantum dots (QDs) with a diameter of 4.36–5.52 nm were rapidly cleared by renal clearance in mice [173,182], QDs >8 nm in diameter did not show the renal clearance but exhibited substantial accumulation in the liver. Glomerular filtration is also influenced by other properties such as charge, shape, and deformability of filtrate. For example, anionic glycolated Fab fragments showed significantly less renal filtration compared to cationic glycolated Fab fragments owing to the electrostatic repulsion between the anionic Fab fragments and the anionic

**FIGURE 9.6** Structure of a nephron. (a) Schema of the nephron, (b) glomerulus in the nephron (*Source:* Modified from Reference [161]), (c) SEM of the podocytes in the glomerulus (*Source:* Reproduced with permission from Reference [178]).

membrane of the glomerular capillary walls [183]. Opsonization stimulated by the surface charge of nanoparticles increases the size, which precludes renal filtration [173]. On the other hand, flexible Ficoll and asymmetrically shaped dextran demonstrated higher renal filtration efficacy than globular proteins, even though their sizes (4.6 and 5.5 nm, respectively) are relatively larger than that of the proteins (3.75 nm) [184]. Although these studies used biological molecules, the results are applicable for nanoparticles in renal clearance.

## 9.4 STRATEGIES TO MINIMIZE THE BIOLOGICAL CLEARANCE OF NANOPARTICLES

Since the emergence of nanoparticles in the 1950s, various strategies to minimize their biological clearance have been developed. Some of them are highlighted in the following discussion.

### 9.4.1 Chemical Cross-Linking

As we have discussed earlier in Section 9.3.1.2, polymeric micelles are unstable under physiological conditions. To solve the problem, various covalent cross-linking methods have been introduced such as photo cross-linking [185] and disulfide cross-linking [186].

There are generally three cross-linkable locations for a triblock copolymer micelle: shell, interface, and core [187–190]. However, to maintain the surface properties and increase drug loading capacity of the micelle, cross-linking is typically done at the interfacial positions [191,192]. Another type of cross-linked nanoparticle is a nano-sized hydrogel (e.g., Pluronic polymer), of which stability can be readily increased by manipulating the cross-linking degree of the nanogel matrix [193,194].

### 9.4.2 Surface Modification

The surface properties of nanoparticles greatly influence their degree of opsonization and biodistribution. For example, neutral or weakly positive nanoparticles are shown to evade opsonization [81,108]. Also, the hydrophilic surface of nanoparticles helps them to escape opsonin-mediated macrophage capture [195,196]. PEG, a nonionic hydrophilic polymer, is widely used to increase hydrophilicity of nanoparticles. Brush configurations of PEG on nanoparticle surfaces reduce protein adsorption. The resistance to protein adsorption greatly increases the blood-circulation time of PEGlyated nanoparticles [9,12,197,198]. However, proteins like albumin, α-chymotrypsin, and hen-egg-white lysozyme can adsorb to the PEG-coated surfaces by forming hydrogen bonding interactions between their carboxyl groups and oxygen atoms in PEG [199–201]. Despite this protein adsorption, PEG surface coating is still the most widely accepted method to reduce opsonization onto nanoparticles. On the other hand, albumin-coated liposomes have demonstrated more prolonged circulation time in blood compared to PEG-coated liposomes, indicating that albumin coating can prevent the adsorption of other proteins more efficiently [202]. Therefore, various albumin-coated nanoparticles have been developed to extend their circulation time in blood [203,204].

### 9.4.3 Control of the Size, Shape, and Deformability of Nanoparticles

The size of nanoparticles is a key attribute that can be manipulated in order to reduce the biological clearance associated with anatomical fenestrations discussed earlier. Although the vascular heterogeneity across different animal models needs to be considered, the diameter range 100–200 nm has been considered an appropriate size in rodent models for both long-term circulation and passive accumulation in tumors [22]. Other properties of nanoparticles such as shape and deformability (flexibility) are also believed to play a role [83,84]. Recent advances in nanotechnology such as the template technology have enabled the development of particles with various sizes and shapes [205,206]. The template technology, which utilizes a template for making homogenous nanoparticles in size and shape, has been used to investigate the effect of particle shape on the phagocytosis by macrophages [207,208]. Macrophages contacting elliptical shaped particles along their major axis rapidly phagocytosed the particles within 6 min, while macrophages that initially contacted the same particles along their minor axis did not internalize the particles. This result suggests that macrophage uptake depends on the particle shape upon initial contact. Another

example pertaining to the effect of nanoparticle shape on biological clearance is filamentous micelles (filomicelles) that have two-dimensional shape (~18 μm in length and ~20–60 nm in diameter). These filamentous micelles exhibited a significantly prolonged blood circulation time (circulation half-lives: ~5 days) and improved drug delivery [30,209]. This shape not only facilitates micelles passage through RES organs such as the spleen and liver but also minimizes their internalization into macrophages. In addition, red blood cells (RBCs) mimicking polymeric particles have recently been engineered using a poly(lactic-*co*-glycolic acid) (PLGA) RBC-shaped template [210]. Although the deformability of these particles was less than that of mouse red blood cells, it was still more flexible than spherical PLGA particles due to their special shape. These particles also demonstrated oxygen and drug carrying capabilities [210]. Another recent study on the deformability of particles showed that micro-sized *N*-isopropylacrylamide (NIPAm) hydrogel particles (~1 μm in diameter) were able to pass through membrane pores at least 10 times smaller in size [211].

It was also reported that the difference in deformability of nanoparticles affected how the nanoparticles were internalized into macrophages [212]. In this study, soft nanoparticles were preferentially internalized via macropinocytosis while rigid nanoparticle uptake was found to be mediated by clathrin-mediated routes. As for nanoparticles with intermediate flexibility, they were internalized via multiple mechanisms. Furthermore, soft chitosan nanoparticles have shown prolonged blood circulation and higher tumor targeting efficacy compared to rigid chitosan nanoparticles [11]. Chitosan nanoparticles with higher degree of substitution of 5β-cholanic acid have demonstrated lower deformability and, thus, higher accumulation in the liver and spleen even though they had a similar particle size (300–400 nm).

## 9.5 FUTURE PERSPECTIVES

We have discussed mechanisms by which nanoparticles are biologically cleared from the body and current strategies to enhance the blood-circulation and tumor targeting effect of nanoparticles. The surface properties of nanoparticles are indirectly related to their blood clearance through plasma protein adsorption and opsonization, while physical properties such as size, shape, and deformability directly impact the removal of nanoparticles via the filtering organs. To extend the retention time of nanoparticles in blood circulation, a number of strategies manipulating the physiochemical properties of nanoparticles have been developed. Nevertheless, the fraction of nanoparticles that actually reach the target tissues still remains very small (~5%), and the majority of administered nanoparticles are found in the RES organs [213].

To overcome this critical challenge, it is necessary to revisit nanoparticle-based delivery strategies and key factors in the design of nanoparticles. One of the most important prerequisites in the design of a nanoparticle system is to stably retain the loaded drug in blood circulation before accessing cancer cells. Disintegration of nanoparticles by plasma protein adsorption is the first clearance mechanism encountered by the systemically administered nanoparticles. A vast majority of nanoparticle

studies focus on postextravasation events such as cellular uptake and intracellular trafficking, but what is the use if most drug has leached out of the system and blank nanoparticles finally reach the targets? Without solving the first problem, targeted drug delivery strategies will have difficulty in taking the next step.

In this regard, the absence of appropriate techniques to investigate whether the nanoparticles remained intact after systemic administration is the major obstacle in the development of new nanoparticle systems. Optical imaging of fluorescently labeled nanoparticles can provide information on pharmacokinetics and biodistribution of the nanoparticles; however, from this technique it is not obvious whether the fluorescent signals come from the intact nanoparticles loaded with drug or disintegrated pieces of nanoparticles. Fluorescence imaging of labeled nanoparticles does not provide sufficient evidence that the nanoparticle has been successfully delivered to the tumor. In an effort to overcome these limitations, our group has designed and synthesized disulfide cross-linked nanoparticles [214]. Using FRET imaging, we monitor the intactness of these nanoparticles in blood vessels and tissues spatiotemporally. The FRET imaging has allowed us to prove that our nanoparticles could stably retain anticancer drugs in bloodstream and increase its blood half-life and delivery to tumors.

*Department of Pharmaceutics, University of Utah, Salt Lake City, UT, USA*

## 10.1 INTRODUCTION

It has been 40 years since the United States Congress passed the National Cancer Act, which directed a great deal of effort into research combating cancer. Since that time, only modest gains have been made in reducing cancer mortality rates in the United States and elsewhere, and the most significant gains have come as a result of prevention campaigns and declining smoking rates [1,2]. Table 10.1 shows that death rates for many cancers have actually increased since 1975 due to rising incidence rates. A major challenge facing researchers has been multiple drug resistance (MDR) in solid tumors [3–6]. Multiple drug resistance is defined as the simultaneous resistance to a wide range of drugs that are unrelated in structure or mechanism of action, and is encountered in up to 80% of nonresectable and 40% of all cancer cases [7,8]. The presence of MDR markers in a patient is strongly associated with poor clinical outcomes [9]. The mechanisms of MDR are extremely varied and can include both chemical and physical barriers to drug action. An MDR tumor generally displays some combination of several MDR phenotypes. The expression of these phenotypes may also vary from cell to cell within a tumor [10].

**TABLE 10.1 Cancer Incidence, Survival, and Death Rates in the United States for the Years from the Mid-1970s to Early 2000s**

| | Incidence Rates[a] | | Mortality Rates[b] | | Survival Rates[a] | |
|---|---|---|---|---|---|---|
| | 1975 | 2003 | 1975[c] | 2000–2004 | 1975 (%) | 2003 (%) |
| All sites | 400.4 | 472.9 | 162.2 | 192.7 | 48.9 | 66.7 |
| Brain, nervous system | 5.9 | 6.6 | 3.8 | 4.4 | 23.0 | 33.7 |
| Breast | 105.1 | 126.5 | 14.6 | 14.5 | 75.5 | 89.9 |
| Colon and rectum | 59.5 | 50.6 | 21.7 | 19.4 | 48.7 | 65.6 |
| Leukemia | 12.8 | 13.3 | 6.6 | 7.5 | 33.4 | 55.6 |
| Lung and bronchus | 52.3 | 64.5 | 36.8 | 54.7 | 11.5 | 16.0 |
| Non-Hodgkin lymphoma | 11.1 | 20.6 | 4.7 | 7.6 | 46.0 | 70.2 |
| Ovary | 16.3 | 13.6 | 4.7 | 5.0 | 33.7 | 44.1 |
| Pancreas | 11.8 | 11.6 | 8.6 | 10.6 | 3.0 | 4.8 |
| Prostate | 94.0 | 169.0 | 8.4 | 10.5 | 66.4 | 99.4 |

Incidence and mortality rates reported as per 100,000 population per year. Survival rates are the percent of patients alive 5 years from diagnosis.

[c]As reported in Reference [11].

Many innovative strategies are in development to overcome individual resistance mechanisms. Most modern drug delivery technologies use nanoparticles as the main delivery platform because of their versatility in both form and function. New treatments are frequently successful in overcoming individual drug delivery barriers (such as resistance mechanisms) and show promise in preclinical studies, but successful application of these technologies in a clinical setting has been rare. Transferring new technologies from laboratory to clinic may require a broader perspective in formulating a drug delivery strategy. Drug carrier characteristics should be optimized to deliver the highest concentration possible from drug administration to drug action, rather than narrowly focus on singular characteristics.

This chapter outlines major mechanisms of drug resistance in tumors, emphasizing the contribution of each mechanism to the whole classification called MDR. The chapter then samples innovative strategies to circumvent or overcome these resistance mechanisms.

## 10.2 PATHWAYS TO DRUG RESISTANCE

An effective cancer treatment must deliver sufficient quantities of drug to its site of action for a sufficiently long period of time to allow drug action to be effective. Otherwise, the treatment will fail to annihilate the cancer regardless of the drug's predicted effectiveness. Achieving a lethal drug dosage at the intracellular site of action for all cancerous cells in a tumor is the perennial challenge in applied drug delivery research. The difficulty of drug delivery arises from the relatively large

**FIGURE 10.1** Before reaching an intracellular site of action, a drug must first pass through several stages of drug distribution. The first is systemic circulation, which distributes the drug carriers throughout the entire circulatory system. In this stage, carriers are subject to clearance through renal filtration or the MPS. A small number of particles will avoid clearance and extravasate out of the disorganized neovasculature into the interstitial space of the tumor. Drug carrier concentration in the tumor may be high relative to other tissues due to the EPR effect but most of the administered drug will not encounter the tumor. Once in the tumor the drug carriers must pass through the tumor interstitial space and extracellular matrix to encounter a cell. The final phase of distribution involves crossing the lipid bilayer membrane to enter the cell then diffusing to the site of action. Drugs targeted to the nucleus must also enter the nuclear envelope. (*Source:* Adapted from Reference [10] and modified.)

distances and diverse environments through which an individual drug particle must traverse before reaching its target. The total path of a drug can be summarized in Figure 10.1, showing the various environments a particle must travel through before an intracellular target may be reached.

### 10.2.1 Resistance of the Tumor Microenvironment

A great deal of drug resistance is conferred to tumors by characteristics of the tumor microenvironment which prevent a drug from ever reaching the subcellular site of action. Most cancer therapeutics are administered via intravenous injection and within minutes are distributed throughout the entire circulatory system. The first major barrier to drug delivery is to move the drug out of the circulatory system and into the tumor before the drug can be cleared by renal filtration [12] and the monocyte phagocyte system (MPS) [13]. Long circulating particles have the opportunity to collect in the tumor by means of the enhanced permeability and retention (EPR) effect, which is the tendency of drugs to preferentially accumulate in a solid tumor due to the tumor's leaky vasculature and poor lymphatic drainage [14,15]. The EPR effect is widely used in modern drug therapeutics, but its usefulness can be mitigated by several countervailing trends [16].

To take advantage of the EPR effect, a drug delivery system must be long circulating, which generally means using large particles which are able to avoid renal filtration modified with a polymer such as poly(ethylene glycol) (PEG) to slow phagocytic uptake [17]. Unfortunately, large particles are less able to extravasate into the tumor interstitium from the capillaries [18]. Thus, there is a trade off between extended circulation half-life and tumor extravasation [19].

Extravasation is further limited by the elevated hydrostatic pressure of the tumor interior, which can sometimes nearly equal the microvascular pressure, severely diminishing the driving force for extravasation into the tumor [17]. This elevated interstitial pressure is a result of the leaky blood vessels that freely allow proteins and other solutes normally excluded by the capillaries of normal tissues. This causes a higher osmotic pressure in interstitial space of the tumor and results in edema [20]. The additional water cannot be cleared because the lymph vessels are often destroyed by a high static pressure resulting from rapidly dividing cells in the limited tumor space [21]. Volume expansion cannot equalize the pressure because of the dense highly cross-linked extracellular matrix (ECM) of the tumor [22].

The pressure at the tumor periphery is lower than that in the center of the tumor creating a driving force for convective flow from the tumor center to the outside [23]. The vasculature is not uniformly distributed in the tumor but is mostly concentrated at the tumor periphery. This is because the solid stress of the tumor destroys the original blood vessels [24], which must be replaced by new vasculature through angiogenesis. These new vessels form from existing vessels outside the tumor and are disorganized, rarely penetrate to the tumor center, and leave large spaces between capillaries [25–27]. This distance becomes a large diffusive barrier and results in chronically hypoxic and undernourished regions in the tumor, which can be seen in Figure 10.2 [28], which is aggravated by the convective flow away from the center of the tumor. This presents a critical challenge for researchers to consider because the conditions of the hypoxic regions select for the most dangerous cell phenotypes such as aggressive growth and metastatic behavior, but these are the very cells least likely to be exposed to lethal drug concentrations [29].

Diffusion is made more difficult by the dense collagen network of the tumor, which may slow or even stop the movement of large particles entirely [30,31]. In this capacity, the collagen matrix can be considered a gate or filter, physically excluding some particles based on size. Those particles that are not excluded must travel a highly tortuous path navigating both the collagen fibers and the extremely dense cell mass. This tends to exacerbate the distance barrier to particle diffusion.

### 10.2.2 Cellular Resistance

Once a drug reaches its site of action, it must enter the cell and reach the site of action before it can be effective. Drug-resistant cells have several mechanisms that can prevent the drug from entering the cell and distributing to the target site. One of the principal and best understood mechanisms of MDR is the active efflux of small molecule drugs by membrane-bound, nonspecific, ATP-driven molecular pumps, of which P-glycoprotein (Pgp) is the most common [32–35]. Pgp pumps are normally

**FIGURE 10.2** Angiogenesis originates from existing blood vessels outside the tumor. New blood vessels tend to be highly irregular and disorganized; they also permeate primarily at the tumor periphery rather than penetrating directly into the tumor interior. This leaves some cells distant from the nearest capillaries creating hypoxic regions in the interior regions of the tumor. Also note that the pressure gradient runs toward the outside of the tumor, so a slight convective flow is expected to run away from the tumor core.

found in the liver, pancreas, kidney, colon, testes, and jejunum of healthy tissues and play an important role in protecting and detoxifying cells commonly exposed to toxic environments [36,37]. It is part of a large family of proteins with similar functions encoded by the MDR1 gene known as the ATP-binding cassette (ABC) family [38]. Pgp can transport a large variety of unrelated compounds from the membrane to the cell exterior and is capable of maintaining large concentration gradients across the cell membrane [39,40].

Another mechanism for drug efflux not related to the ABC pumps is the lung resistance-related protein (LRP) most commonly found in lung carcinomas [41]. LRP is not a membrane pump, but rather a major vault protein. Vaults are thought to be associated with the nuclear pore complex and regulate entry into the nucleus. Drugs can be sequestered into a vault at the nuclear pore complex and then transported into the cytoplasm where it is subsequently exocytosed [42].

Many drugs may also be sequestered into a number of intracellular compartments especially the mitochondria, Golgi, and endosomes. Drugs collect into these compartments by pH partitioning and active pumping in the case of endosomal vesicles and by increased solubility in membrane-rich organelles such as the Golgi and mitochondria [43]. The drug sequestration can be quite marked due to large solubility differences [44]. These drugs are held away from their sites of action until they can be either metabolized or removed from the cell entirely via exocytosis.

Cells can gain resistance to drugs targeting specific signaling pathways by modifying part of the targeted chemical pathway to compensate for the drug's action. The most commonly encountered forms of chemical resistance modulate key pathways targeted by cancer therapeutics such as the apoptosis pathway. Almost all cancers must shut down the protein p53, which is a key choke point in apoptosis [45]. The cell is rendered more resistant by upregulation of antiapoptosis factors such as bcl2 [46,47]. DNA repair mechanisms may also be upregulated to weaken apoptotic signals triggered by damaged DNA [48].

Resistance may also be conferred by increasing the cellular metabolism of the drug [49]. Glutathione is a key component of the glutathione detoxification system, which can be used to metabolize drugs in the cytoplasm [50]. It operates by binding to the toxic substance by means of a sulfur bond [51]. This mechanism can confer resistance to a number of anticancer compounds [52–55]. It can also act as an antioxidant, which would confer resistance toward drugs designed to generate free radicals [51].

### 10.2.3 Perspective on Drug Resistance

This review of MDR mechanisms is not meant to be comprehensive and does not provide depth on any of the mechanisms described. The intent of this brief description of MDR mechanisms is to provide perspective on the breadth of the challenge in designing a drug delivery system to overcome the diverse mechanisms of resistance. Any approach to combat MDR that only takes a single mechanism into account is unlikely to succeed in a clinical setting. Oftentimes, a delivery strategy targeted to overcome one MDR mechanism will leave it especially vulnerable to another. For example, using large particles as drug carriers will help increase circulation time and accumulation in the tumor; however, once in the tumor the diffusion of large particles is severely limited and is unlikely to reach the majority of tumor cells. Large particles become helpful again as a way to circumvent Pgp pumps because they can cross the cell membrane via endocytosis rather than diffusion. All drug delivery systems must compromise between these countervailing effects.

Different cells within the same tumor will have different phenotypes, express Pgp at varying levels, have different apoptotic thresholds, or metabolize toxins at different rates [56]. In the face of treatment, natural selection favors resistant cell types upon tumor recurrence [57]. Any plausible technology to combat MDR should account for the diversity of mechanisms present in a single tumor and seek to combat the cancer as holistically as possible. Otherwise, each successive treatment will increase the risk of a more resistant recurrent tumor.

## 10.3 COMBATING MDR

The diversity of MDR mechanisms requires that any drug delivery system designed to combat MDR be extremely versatile. Nanoparticles are among the most versatile tools available to researcher for combating cancer [58]. Platforms for nanotherapeutics can take many forms as shown in Figure 10.3. The different classes of these nanoparticles include dendrimers [59], linear polymeric carriers [60], inorganic nanoparticles [61], micelles [62], polymersomes [63], and liposomes [64]. Attaching drugs to or encapsulating them in nanocarriers helps solubilize and stabilize most drug formulations [65]. The large particle size of drug delivery systems excludes clearance by renal filtration, which increases circulation time, allowing for drug

**FIGURE 10.3** Various physical forms of nanoparticles used in cancer therapy. (a) Dendrimers are highly branched polymers that form into a tree or bush-like structure. (b) Linear macromolecular carriers are composed of a degradable polymer backbone to which drugs or targeting moieties can be attached. (c) Inorganic nanoparticles can be made from various metals or other compounds such as SiO; the surface of these particles is often modified with PEG, targeting moieties or drugs. (d) Micelles are often composed of block copolymers bearing a hydrophilic and hydrophobic region. The hydrophobic region of these polymers interacts in aqueous environments forming a stable core into which drugs can be loaded. The hydrophilic region of the polymer can be modified in other ways. (e) Polymersomes are generally made from triblock copolymers that assemble to form a vesicular structure with a hydrophilic core. Compounds may be loaded into both the hydrophilic and hydrophobic regions. (f) Liposomes are similar in structure to polymersomes but are made using phospholipids similar to those in natural lipid bilayer membranes.

accumulation through the EPR effect. The circulation time of nano-sized drug carriers can be further enhanced by modifying the surface to inhibit MPS uptake. The most common and effective surface modification for increasing circulation time is grafting PEG on the particle surface. PEG is a highly hydrophilic polymer that extends out and sterically prevents proteins from adsorbing the particle surface and MPS uptake [66]. Other modifications can also be added to a nanoparticle to confer the desired properties. Targeting moieties are a common modification designed to increase tumor localization and cellular uptake [67]. Drug can also be attached to the surface of the particle or be stored in the internal hydrophobic or hydrophilic compartments. This versatility makes co-delivery of multiple compounds with different characteristics possible [68]. In addition to drug compounds, dyes or other imaging agents can also be included with the drug carrier. This provides the capability to image the tumor during the course of treatment, a capability known as theranostics [69]. The ability of nanotherapeutics to carry on such a broad range of function is what brings it to the forefront of modern cancer research.

Long circulating nanoparticles are, in most instances, able to accumulate preferentially in the tumor due to the EPR effect [70,16]. From the point of entry into the tumor, however, the strategies of drug delivery may vary tremendously. The majority of methods are targeted to combating ABC pumps such as Pgp, which are generally considered the principal mechanism of MDR [11]. Efflux from ABC pumps is sometimes even described as synonymous with MDR [71,72].

The main strategies for combating the ABC pump mechanism of multiple drug resistance are to either circumvent it by bypassing membrane diffusion or by delivering Pgp disabling compounds with the drug. The capacity of a nanoparticle to be a platform for multiple compounds provides the capability to combat other MDR mechanisms. Co-delivery of anticancer drugs with apoptosis modulators can be used to increase drug sensitivity, and co-delivery of the nanoparticles with collagenases can be used to enhance drug penetration into the tumor.

### 10.3.1 Bypassing MDR by Endocytosis

ABC pumps are membrane-embedded proteins which capture and then efflux small molecule compounds while dissolved in the membrane. The process of diffusing across the membrane exposes small molecular weight drugs to efflux [73]. Encapsulating the drug in a large particle allows bulk uptake through endocytic pathways, thus bypassing MDR pumps such as Pgp. Bringing the intact drug carrier into the cytoplasm through endocytosis and phagocytosis enables the drug to be released directly into the cytoplasm resulting in a higher sustained cytoplasmic concentration [74].

A major challenge to achieving sufficiently cytotoxic-free drug concentrations is for the cell to uptake a sufficient quantity of drug carriers. The rate of endocytosis is dependent on a number of factors including size, shape, and particle–membrane interactions. Optimal particle uptake appears to occur for particles in the 30–50 nm diameter range [75,76]. The aspect ratio of the particles also plays a role in active uptake by the cell. Studies done with silica nanoparticles have shown that slightly

elongated particles (with an aspect ratio of 2.1–2.5) show the highest cellular uptake rates [77,78].

Active targeting improves cellular uptake by conjugating ligands to the nanoparticle, which will interact with receptors on the cell membrane. These targeting moieties can increase the frequency and strength of membrane interactions, giving greater likelihood of internalization. Targeting moieties are often antibodies against proteins that are generally overexpressed on cancer cells. A broad range of antibodies can be used depending on the cancer type [79,80]. Among the most common targets for active targeting are folate receptors [81] and Her2 receptor [82], which are overexpressed in many cancers. Targeting to specific protein receptors suffers from the differential expression of these receptors within a single tumor. An example of this phenomenon is the drug Trastuzumab (Herceptin®) which targets the Her2 antigen which is overexpressed in some 20–30% breast cancer patients. The use of this treatment governed by the immunohistochemistry (IHC) scoring system which rates the overall Her2 expression in a tumor. The highest score under this system is assigned to tumors in which only 10% of tumor cells stain strongly for Her2. Among patients with the highest levels of Her2 expression, only half appear to benefit from Herceptin targeted treatment [83]. Other targeted cancer treatments also must labor under this burden of differential protein expression in cancer cells.

Nonspecific targeting can also be used to enhance cellular uptake. The cell penetrating peptide TAT is associated with HIV infectivity and allows it to infect a wide variety of cells [84]. The effectiveness of TAT at entering cells has led to its use as a means of encouraging endocytosis in drug delivery [85]. TAT works in an enormous variety of cells, but this lack of specificity risks increasing the nonspecific toxicity of the drug [86]. Specificity can be increased (and negative side effects reduced) by shielding the TAT until the drug carrier reaches the tumor site. Deshielding can be tied to environmental stimuli unique to the tumor, such as acidity or hypoxia [87].

The effectiveness of a drug carrier is in part dependent on the mechanism by which it is internalized. Nanoparticles can enter the cell in a variety of ways including diffusion, clathrin-mediated endocytosis, caveolae-mediated endocytosis, and pinocytosis [88]. The means by which the particle enters the cell will affect the drug release and intracellular distribution of the drug. Particles that diffuse across the membrane will emerge near the membrane on the intracellular side. Drug release then is likely to occur close to the membrane where the drug molecules can then reenter the membrane by diffusion and be effluxed [89]. Most drug carriers are actively brought into the cell through either endocytosis or phagocytosis and then enter the endocytic pathway [90]. The lysosome is the end stage of the endocytic pathway and presents a severe problem for drug release. The harsh, acidic, and degradative environment in the lysosome is designed to degrade any phagocytosed particles before they are allowed entry into the cytosol to prevent harm to the cell [91].

Avoiding the lysosome is critical for effective delivery from endocytosed particles. Caveolae-mediated endocytosis operates with a unique pathway that may not involve the lysosome [92,93], suggesting a strategy for circumventing drug destruction by targeting the caveolae-mediated pathway [94]. Targeting a single endocytic

pathway can be challenging; pinocytosis is a common uptake mechanism and is nonspecific. Unfortunately, the data was unclear as to whether the lysosomal phase is actually avoided [95,96]. If the lysosome is the end result of all endocytic pathways, it is necessary to design the drug delivery system to exit the endosome before they can merge with the lysosome. pH-sensitive micelles provide one strategy for endosomal escape [97,98]. Micelles can be tuned to break up at the endosomal pH releasing the contents into the vesicle. The sudden release of solute drug and micelle polymer in the endosome causes a spike in osmotic pressure driving water to rush into the vesicle. The vesicle may then swell to the breaking point, emptying the contents of the vesicle directly into the cytoplasm.

### 10.3.2 Co-Delivery of Drugs with Other Compounds

One of the major strengths of using nanoparticles as a platform for drug delivery is the ability to deliver finely tuned doses of multiple drugs into the local environment. Many nanoparticle drug formulations have been designed and studied to target MDR by co-delivering chemotherapeutic agents with chemosensitizers, oligonucleotides, proteins, and so on. Co-delivery of drugs with other compounds can allow synergistic cooperation, maximizing the effect of the delivered drug.

Drugs can be incorporated in nanoparticles in a variety of ways, which can enable various strategies for combinational drug therapy [99]. Drugs can be covalently linked to the nanoparticle or linear polymer chains, often by a degradable linker which is tuned to release the drug at the desired time [100]. Often, the drug is stored in hydrophilic and/or hydrophobic compartments of the nanoparticle. Micelles often store drugs in their hydrophobic core, and liposomes and polymersomes can store dissolved hydrophobic drug in the membrane and can additionally store hydrophilic drugs in the aqueous center [68]. Drug can also be physically entrapped in a polymer mesh such as in a dendrimer or hydrogel [101,102].

Co-delivery of drug with a Pgp modulator is a common strategy to combat ABC pump-mediated MDR [103]. This strategy has been employed for more than 30 years since Pgp was identified as a major MDR mechanism. Several generations of ABC pump modulators have been developed to deal with the weaknesses of the first modulators [104]. Use of these modulators has effectively increased the intracellular concentration and drug sensitivity of the cells [105]. On the other hand, ABC pumps are also important features of cells in healthy tissues, which are routinely exposed to toxins such as the liver, kidneys, and intestines [36]. Therefore, using Pgp modulators leads to nonspecific toxicity issues that limit the clinical relevance of the method [106]. Third generation modulators, currently being developed, have been shown to more effectively sensitize cells while maintaining tolerable toxicity [107,108]. Drugs delivered in nanoparticles collect in the liver, kidney, and spleen where ABC pumps play an important role in detoxifying healthy tissues. This makes ABC pump modulation a less than ideal tactic unless true tumor targeting can be achieved.

One important strategy to mitigate emergence of MDR is to deliver drugs of very different structures and functions simultaneously [68]. The ability to incorporate

drugs in a nanoparticle platform by several mechanisms makes it possible to deliver disparate drugs. This strategy is used in agriculture, where applying multiple pesticides to a field simultaneously slows evolution by creating divergent pressures and mitigating the advantage of individuals with resistant traits [109]. Furthermore, well-chosen drug combinations can take advantage of synergistic effects among drugs to increase sensitivity of the target cells allowing the total amount of drug to be minimized [110].

The sensitivity of cells can be greatly increased by co-delivering apoptosis modulators with the drug. Apoptosis modulators can take the form of antisense oligonucleotides or other chemical compounds such as ceramide [111]. The antisense oligonucleotides generally work by knocking down expression of proteins, such as bcl2, which inhibit the apoptosis pathway. The resulting drug combination can be as much as 100-fold more potent than using drug alone [112]. Of course the apoptosis pathway is common to all cells, so carefully targeted drug release is again a challenge as lowering the apoptotic threshold in normal cells could lead to tissue damage.

Nanoparticles can also be used to modify the tumor microenvironment and improve drug distribution through the tissue. The most commonly explored means of improving drug distribution at the tissue and microenvironmental levels is to deliver collagenases with the nanoparticles, which can degrade the collagen matrix of the tumor tissue [113,31]. Degrading the collagen matrix has a twofold benefit. The most obvious is that the dense network of protein fibers can be a significant barrier to particle diffusion, especially the relatively large particles used as drug delivery systems. Drug bound nanoparticles fail to move more than a few microns from the point of extravasation into the tumor. The collagen matrix also contributes to the elevated interstitial pressure observed in most tumors by preventing volume expansion and providing resistance to bulk fluid flow [30]. The interstitial pressure in the tumor can approach that of the microvasculature, thus moving the convective driving force for extravasation of the capillary into the tumor and reducing overall tumor drug accumulation [24,114,115]. Degradation of the tumor protein matrix temporarily lowers the oncotic pressure of the tumor and restores the driving force for extravasation [115]. Collagen matrix degradation has also been shown to improve diffusion within the tumor tissue [31], thus improving overall distribution. One concern with using this approach is that a host of cells may be released and metastasize. Further study is needed to evaluate this risk.

### 10.3.3 Stimuli-Based Methods

Nanoparticles may be designed to respond to a variety of stimuli. Micelles sensitive to surrounding pH were discussed as a means to deliver drug directly to the cytoplasm of the cell in a previous section [98]. Nanoparticles may also be designed to respond to external stimuli such as radiation, ultrasound, and temperature, which can then be used in the clinic to localize drug release, sensitize cells, or directly kill cells [116–118]. Cancer treatments relying on external stimuli have some tremendous advantages over more passive treatment methods. The main

advantage of using external stimuli as a trigger for treatment is the level of control it offers the physician. The therapeutic effect occurs precisely where and when the physician determines is appropriate.

Photothermal ablation is a form of external-stimuli-based nanotherapy and has an additional advantage of not requiring drug sensitive tumor cells. Treatment by photothermal ablation is accomplished by administering nanoparticles to the patient, then focusing particular wavelengths of light on a tumor. The light is then absorbed by the nanoparticles, causing heating of the surrounding tissue [119]. Ablative therapy can result in local temperatures within the tissue approaching the boiling point of water [120]. This gives ablative therapy the advantage of not requiring cellular entry, and the specificity of the treatment can be consciously controlled by the practitioner. Particle distribution can be a significant challenge just as for drug-based therapies; however, heat diffusion may be less hindered than particle diffusion depending on the tumor type and composition [121]. The effectiveness of the therapy depends in part on the ability to predict and control the heat distribution, which generally requires high-level mathematical modeling of the tumor heat profile during treatment [122,123]. Achieving sufficient tissue penetration to treat deep tumors is also a distinct challenge for ablation therapy, but a broad range of stimuli have been shown to accomplish therapeutic heat ranges with different particles providing a large range of treatment options [116,123,124]. In situations where necrosis is undesirable, more gentle heating (in the 45°C range) can be used to sensitize cells to traditional drug therapies [125]. Cell sensitization in hyperthermic conditions results from the inhibition of intracellular repair mechanisms due to heat shock [126].

There exist other forms of external-stimuli-based therapies designed to improve therapeutic efficacy. This includes using ferromagnetic particles, which can actively move deeper into a tumor in response to a magnetic field [127], and ultrasound-sensitive drug packets, which can be released specifically at a specific site with focused ultrasound [117]. Many of these therapies have theranostic potential, meaning that the particles used can be simultaneously used as imaging contrast agents to visualize the tumor even as the treatment is occurring [128].

Unfortunately, these methods are only able to treat "visible" tumors, or tumors that are large enough and can collect enough particles to stand out against the background noise for imaging. Smaller tumors and metastatic cells must be treated by more traditional drug-based therapies. Also, the inorganic nanoparticles, which are frequently used for stimuli-based therapies, are not readily cleared by the body and may accumulate permanently in the liver and spleen posing serious long-term toxicity issues [129].

## 10.4 FUTURE PERSPECTIVES

MDR is a grave development in the lifetime of a tumor. MDR tumors are generally composed of more resilient and potentially more metastatic cells, which lead to a poor prognosis for a patient. The diversity of mechanisms contributing to MDR

creates a difficult problem in designing effective strategies to treat resistant cancers. Research has revealed an impressive arsenal of technologies capable of combating individual resistance mechanisms. Unfortunately, the multimodal nature of resistance can severely limit the effectiveness of narrowly designed drug delivery systems. This in part explains the limited success of modern therapies in clinical settings. The next step in drug delivery to resistant tumors will require a more holistic view of distribution and resistance, accounting for each stage of delivery from circulatory distribution to efficacy at the site of action. This approach may require trade-offs to cope with the exacting demands of tumor delivery and distribution, cellular uptake, and drug efficacy. Designing drug delivery systems from a comprehensive perspective requires a more profound understanding of the interplay between the MDR mechanisms and drug delivery.

## 11.1 INTRODUCTION

Many drug molecules have intracellular sites of action and, therefore, require entry into the cell to exert their therapeutic effects. These include both macromolecules such as nucleic acids and small molecules such as taxanes. However, the cell membrane presents a formidable barrier to the entry of many drugs, either because the molecules are too large and/or polar to diffuse across the membrane (nucleic acids, proteins) or because they are actively pumped out of the cell by membrane-bound efflux transporters (paclitaxel, doxorubicin). Delivery systems that facilitate the intracellular accumulation of these drug molecules could enhance their therapeutic efficacy. Additionally, it has become obvious that for certain drugs, the localization into specific intracellular organelles is critical for their biological performance. For instance, to achieve effective gene expression, plasmid DNA

needs to be delivered not only into the cell but also into the nucleus. In the past decade, studies from several laboratories have shown that encapsulation of a drug in polymeric nanoparticles can improve its intracellular delivery. This chapter examines the intracellular trafficking of polymeric nanoparticles and the impact of modulating this trafficking on the therapeutic performance of the encapsulated drug.

## 11.2 PATHWAYS OF CELLULAR ENTRY

In order to understand the interaction of nanoparticles with cells, it is imperative to first introduce the lipid bilayer. The cell membrane defines the boundary between cellular contents and the external environment, separating intracellular biochemical activities from the extracellular surroundings. This seemingly excluding barrier is also the major interface where cells exchange information and materials with the surroundings. Phagocytosis and endocytosis are processes that either originate at or involve the plasma membrane to fulfill this mission. Similarly, at the subcellular level, it is again the compartmentalization by lipid bilayer membranes that enable various specialized biochemical processes proceeding simultaneously within the cells without interfering with one another. However, the necessity of exchanging materials and information still holds true at the organelle level. Intracellular membrane systems are involved in sorting and transporting materials within the cell in an orderly manner. Thus, plasma membrane and endomembrane system as a whole constitute dynamic continuums that relay material and information within the cell and with its surroundings. The interplay between nanoparticles and cells with regard to cellular uptake and intracellular trafficking is also intimately related with this dynamic cellular membrane system.

### 11.2.1 Endocytosis: Many Different Versions

Cells acquire large biomolecules and foreign substances that otherwise would be impermeable to the cell membrane through a process termed endocytosis. This term encompasses many different active (energy-dependent) membrane-based uptake processes. The major pathways involved in nanoparticles uptake are illustrated in Figure 11.1 [1]. Receptor-mediated endocytosis is a process by which cells internalize receptor-bound ligands. Clathrin-mediated endocytosis is so far the best-characterized pathway by which cells internalize specific molecules and modulate the expression level of membrane-bound receptors [2]. Morphologically, a salient feature of this endocytic mode is the formation of clathrin-coated pits and vesicles [3]. Recently, it was shown that this form of endocytic activity is initiated through the nucleation of FCHo proteins and various scaffold proteins such as eps15 and intersectin that promote the formation of cell membrane curvature, followed by recruitment of adaptor protein 2 (AP2) and clathrin triskelia [4]. Once the assembly of the clathrin lattice on the membrane is achieved, the scission of the invaginated clathrin-coated vesicle from the cell membrane is triggered. This process is facilitated by the mechanochemical enzyme dynamin, which prefers to localize

**FIGURE 11.1** Principal nanocarrier internalization pathways in mammalian cells. (*Source:* Reproduced from Reference [1] with permission from Springer Science and Business Media.)

to the constricted neck of the clathrin-coated vesicle because of the curvature, to complete the vesicle fission procedure in a GTP-dependent manner, pinching off the vesicle from plasma membrane [5]. The diameter of clathrin-coated pits in mouse epithelial cells ranges from 120 to 150 nm; while in mouse neuron, the diameter of clathrin-coated pits is from 70 to 90 nm [6]. The size of clathrin-coated pits can increase to accommodate the size of cargo [7]. The upper limit observed so far is ~200 nm in the case of clathrin-dependent cellular entry of vesicular stomatitis virus [8], although the definite upper limit in terms of transporting nanoparticles through this pathway is not yet elucidated. Clathrin-mediated endocytosis is involved in the internalization and recycling of transferrin receptor (TfR) and epidermal growth factor receptor (EGFR) [9].

Distinct from the classical clathrin-dependent pathway, several alternative clathrin-independent routes have been identified [10]. Caveolae-mediated endocytosis has recently gained a lot of attention. Despite this pathway's dependence on actin and dynamin for assembly and scission from plasma membrane (similar to the clathrin pathway), caveolae exhibits an invaginated flask-shaped morphology with caveolin-1 as the defining component [11]. In addition, caveolae are also rich in cholesterol and sphingolipid and are similar to detergent-resistant membrane microdomain lipid rafts in lipid composition. It has been suggested that caveolae share a common endocytic pathway with lipid rafts in that both processes are sensitive to cholesterol depletion [11]. The size of caveolae is relatively smaller than clathrin-coated vesicle. The reported diameter range is 50–80 nm under normal physiological conditions [12,13]. Caveolae and raft pathways facilitate the uptake of sphingolipid binding toxins (e.g., cholera toxin and Shiga toxin), albumin, glycosylphosphatidylinositol (GPI)-anchored proteins, growth hormone, and SV40 virus [14].

Macropinocytosis is a tightly regulated, actin-dependent fluid phase process that allows cells to capture materials in close proximity to the cell membrane [15]. This so-called cell drinking process relies on the ruffling of cell membrane, engulfing solute molecules and nutrients from extracellular fluid, followed by the formation of a large vacuole termed macropinosome within the cells [16]. Unlike receptor-mediated endocytosis, macropinocytosis is generally considered a nonspecific sampling process [17]. However, a variety of viruses including vaccinia, adeno, and picorna have been reported to take advantage of macropinocytosis to gain access to cytosol [18]. In addition, macropinocytosis has been proven to be involved in the cellular entry of arginine containing cationic peptides, such as the TAT peptide derived from human immunodeficiency virus (HIV) [19,20].

Phagocytosis is typically considered a procedure for internalization of large particles that are 0.5 μm in size [21]. Phagocytosis is often a feature of distinct cell types. Professional phagocytes, such as macrophages and dendritic cells, typically possess much higher phagocytic ability compared to other normal cell types [22]. As a result, phagocytosis is not considered a major pathway for nanoparticle internalization in non-phagocytic cells. Thus, this chapter does not focus on this topic for the discussion of cellular entry and subsequent intracellular fate of nanoparticles. However, in most cases, it is a significant uptake and clearance pathway when nanoparticles are administered *in vivo* due to the widely documented role of the

**TABLE 11.1 Agents Used to Inhibit Specific Endocytic Pathways**

| Dynamin Dependent | Clathrin | Caveolin | Macropinocytosis | Microtubule Dependent |
|---|---|---|---|---|
| Dynasore | Chlorpromazine<br>Amantadine<br>$K^+$ depletion | Filipin<br>Genistein | Cytochalasin<br>5-(*N*-ethyl-*N*-isopropyl) amiloride (EIPA) | Nocodazole |

reticuloendothelial system (RES) in nonselective elimination of nanoparticles [23]. Nanoparticle aggregates that are too large for endocytosis are likely cleared by professional phagocytes via phagocytosis. Moreover, phagocytosis could serve as a significant pathway for indirect nanoparticle acquisition. When successful intracellular nanoparticle delivery results in cell death, with an anticancer payload for example, the resulting apoptotic bodies and cellular debris will be cleared by professional phagocytes [24]. It is conceivable that a significant amount of nanoparticle components are still present within the apoptotic bodies. Thus, phagocytosis should not be overlooked for its contribution to the disposition of nanoparticles.

Often, several pathways contribute to the cellular uptake of nanoparticles. For instance, by using selective inhibitors to dissect endocytic pathways involved in the uptake of hydrophobically modified glycol chitosan nanoparticles by HeLa cells, caveolae-mediated pathway was found to account for 40% of uptake, clathrin-mediated pathway contributed to 20% of uptake, and another 30% was attributable to macropinocytosis [25]. A list of commonly used agents that selectively inhibit specific endocytic pathways is provided in Table 11.1.

### 11.2.2 Factors Affecting Nanoparticle Uptake into Cells

***11.2.2.1 Size and Shape.*** It is generally accepted that size is the primary determinant of efficiency for the cellular entry of nanoparticles. It was reported that 50 nm gold nanoparticles show maximum uptake efficiency in HeLa cells compared to smaller or larger particles in the tested size range from 14 to 100 nm [26]. This trend was maintained in the presence or absence of transferrin, even though transferrin adsorption did facilitate uptake across the entire size range. Dos Santos et al. studied the effect of wider range of particle sizes (40, 100, 200, 500, 1000, 2000 nm) on the uptake efficiency of carboxyl-modified polystyrene nanoparticles in several cell lines (HeLa, A549 epithelial cells, 1321N1 astrocytes, HCMEC D3 endothelial cells, and RAW 264.7 macrophages) [27]. Regardless of the particle size, macrophages were the most efficient at internalizing the particles. Internalization of nanoparticles was highly size-dependent in all the cell types studied, with uptake efficiency decreasing with increasing particle size.

The size dependence of nanoparticle uptake and the presence of an optimal size for the highest uptake efficiency have been attributed to the smallest wrapping time to generate a suitable membrane curvature around nanoparticle/nanoparticle aggregates [28]. This size is predicted to be about 30 nm, which is in agreement with several experimental observations with both viral and nonviral nanoparticles [29,30].

On the basis of the wrapping time theory, it is also proposed that uptake of nanoparticles with optimal size could occur independent of clathrin- and caveolin-mediated endocytosis. A similar experimental study and mechanistic modeling have been conducted for single-walled carbon nanotubes (SWNTs). The model asserts that a size of 25 nm confers the optimal radius for membrane capture. For nanomaterials with a dimension smaller than 25 nm, clusters could form on the plasma membrane surface to generate sufficient enthalpic contribution via nanoparticle–cell membrane interaction to overcome the membrane elastic energy and entropic barriers related to vesicle formation. It was found that SWNTs demonstrate 1000 times higher endocytosis rate constant ($10^{-3}$ $\text{min}^{-1}$) than spherical gold nanoparticles with the same radius ($10^{-6}\,\text{min}^{-1}$) [31]. Moreover, a length dependence of SWNT uptake has been reported with a threshold of ~189 nm, indicating nanotubes longer than this threshold could not be taken up by cells [32].

Conflicting data have been reported about the impact of shape on cellular uptake. The uptake of rod-shaped gold nanoparticles was reported as being less efficient compared with their spherical counterparts. Cells internalized 5 and 3.75 times more 74 nm and 14 nm spherical gold nanoparticles than $74 \times 14$ nm rod-shaped gold nanoparticles, respectively [26]. In addition, higher aspect ratio (1:5) nanoparticles were taken up poorly in comparison with lower aspect ratio (1:3) nanoparticles. In contrast, a study using cationic, cross-linked poly(ethylene glycol) hydrogel nanoparticles manufactured through PRINT technique has generated opposite results. HeLa cells internalized the high-aspect-ratio cylindrical particles (diameter, $d = 150$ nm, height, $h = 450$ nm) ~4 times greater than the low-aspect-ratio symmetric cylindrical particles ($d = 200$ nm, $h = 200$ nm) [33]. Similarly, greater internalization of larger aspect ratio was observed for mesoporous silica nanoparticles in A375 melanoma cell lines [34]. On the other hand, Meng et al. showed that the internalization of rod-shaped silica nanoparticles in HeLa and A549 cell lines was much greater than that of spherical particles, but rod-shaped silica nanoparticles with aspect ratio of 2.1–2.5 demonstrated the highest uptake efficiency than either longer or shorter length rods. This was attributed to stronger activation by nanoparticles with this particular aspect ratio of GTP-binding protein Rac1, which is activated during macropinocytosis, and the Rho subfamily member protein CDC42 involved in regulating actin polymerization-dependent macropinocytosis processes [35].

***11.2.2.2 Surface Properties.*** The surface characteristic of nanoparticles not only affects cellular uptake but also the intracellular fate following the cellular entry. Characteristics affecting nanoparticles uptake include surface charge, chemical composition, presence of targeting ligand, and the number of ligand molecules.

It is generally thought that neutral charge on the surface minimizes the interaction of nanoparticles with cells, partly because of weaker protein adsorption on the surface of nanoparticles in biological milieu [36,37]. PEGylation (incorporation of poly(ethylene glycol), PEG, chains on the surface) is the most well-established surface modification technique to provide "stealth" capability and improve the pharmacokinetic profile. The neutral and hydrophilic PEG coating

lowers nonspecific protein adsorption, opsonization, and nanoparticle aggregation so that receptor-mediated endocytosis by cells of RES is dampened [37]. On the other hand, charged nanoparticles typically exhibit stronger ability to interact with cells. This is especially true for cationic nanoparticles that are highly charged, although higher cytotoxicity could also be expected [38]. Using an *in vitro* polarized epithelial Madin–Darby canine kidney (MDCK) cell model, it was found that both cationic and anionic nanoparticles are taken up by the epithelial cells through clathrin-dependent pathway and macropinocytosis, followed by significant transcytosis and accumulation at the basolateral membrane. Only a fraction of anionic but not cationic nanoparticles transited through the degradative lysosomal pathway [39]. In the context of *in vivo* distribution, since nanoparticles with high surface charge and larger size are cleared by macrophages more efficiently, 150 nm nanoparticles with slight negative surface charge has been shown to be the most effective in achieving prolonged circulation, a prerequisite for enhanced tumor accumulation [40].

A novel mechanism for how positive surface charge affects nanoparticle–cell interaction was recently proposed. Binding of positively charged nanoparticles to the negatively charged plasma membrane could modulate the membrane potential, induce membrane depolarization, and influx of $Ca^{2+}$ [41]. To take advantage of the fact that positively charged surfaces lead to improved cellular entry, Poon et al. constructed a layer-by-layer nanoparticle system, consisting of quantum dot core, coated with iminobiotin-modified poly-L-lysine inner layer and biotin-functionalized PEG outer layer, bridged by neutravidin. Because of the pH-sensitive nature of iminobiotin–neutravidin interaction, it was expected that the outer PEG layer that conferred long circulating property would be shed in the acidic tumor microenvironment. The subsequent exposure of positively charged poly-L-lysine coating allowed for improved cellular uptake of nanoparticles. The benefit of this strategy was shown *in vivo* in MDA–MB-435 breast cancer model [42].

Another study suggested that it might be possible to modulate the mechanism of cellular entry by tuning the surface properties of nanoparticles. It was reported that 6 nm nanoparticles, decorated with a shell of alternating hydrophobic and anionic hydrophilic ligands in ribbon-like domains, display membrane penetration without bilayer disruption even at 4°C and altered intracellular localization compared to the "isomer" nanoparticle counterpart with identical surface functionalization but completely disordered surface pattern arrangement [43].

### 11.2.3 Targeting Ligand-Mediated Cellular Entry of Nanoparticles

In order to maximize efficacy and minimize off-target side effects, targeting proteins and receptors that are abundantly expressed on malignant cells have been routinely investigated. The mechanism of entry and intracellular trafficking of nanoparticles with the surface-bound ligand could, to some degree, mirror that of the specific target receptors [44]. Although overexpression of several different receptors has been reported, this chapter discusses transferrin and folic acid receptors as prototypical clathrin- and caveolae-based receptors, respectively.

***11.2.3.1 Transferrin Receptor (TfR).*** Uptake of transferrin by TfR via clathrin-coated pit is one of the most well-characterized endocytic processes [45,46]. TfR is overexpressed in a wide variety of cancers [47]. Naturally, numerous groups have chosen TfR-mediated endocytosis as both a targeting and uptake enhancing strategy. Even though the presence of TfR targeting moiety on drug delivery carrier may not necessarily improve the overall accumulation in solid tumor, TfR targeting strategy has shown to significantly improve the amount of nanoparticles localized within cancer cells [48]. The study that provided the first evidence of successful RNA interference in human utilized TfR-targeted nanoparticle as a delivery platform for systemic administration of siRNA [49].

By using a 3-glysidoxypropyltrimethoxysilane (3-GPTMS) linker with epoxy terminal, the surface of mesoporous silica nanoparticles was decorated with Tf in another study. This allowed for enhanced accumulation of silica nanoparticles in TfR transfected HFF cell line compared to the wild type HFF cell line, indicating TfR-mediated endocytic uptake process in TfR overexpressed cells [50]. Cylindrical PEG-based PRINT nanoparticles conjugated with either human Tf or anti-TfR monoclonal antibody was internalized more readily in a panel of six common cancer cell lines relative to nanoparticles labeled with either bovine Tf or isotype control antibody, suggesting the potential for exploiting TfR-mediated endocytosis in improving intracellular delivery in TfR positive tumors [51]. TfR-targeted lipid nanoparticles encapsulated with antisense oligonucleotides against the antiapoptotic factor Bcl-2 were found to be internalized more effectively and possessed much better gene knockdown efficiency in leukemia cell lines than nontargeted lipid nanoparticle and free oligonucleotides [52]. Highest Bcl-2 downregulation and apoptosis-inducing efficacy was found in K562 cell line, which expressed the highest TfR level. The Bcl-2 downregulation and apoptosis induction were blocked by excessive free Tf. Combination of TfR targeting with pH responsiveness is particularly well suited to capitalize on the acidification of endosome subsequent to TfR-mediated endocytosis. Methacrylic acid copolymer complexed with poly(amido amine) (PAMAM) dendrimers and siRNA formed a core-shell polyelectrolyte micelle, which was decorated with anti-TfR Fab (antibody fragment of antigen binding) [53]. Targeted micelles showed stronger uptake by PC-3 prostate cancer cells than nontargeted control, and excess free anti-TfR antibody abolished this difference. Once the anionic portion of methacrylic acid copolymer was neutralized during acidification, polycationic dendrimer core containing siRNA was exposed, followed by endosomal escape and mRNA transcript silencing.

***11.2.3.2 Folate Receptor.*** Unlike other transmembrane receptor proteins, folate receptor is a glycosylphosphatidylinositol (GPI)-anchored membrane protein, potentially associated with lipid raft [54]. Internalization of folate receptor follows a clathrin-independent mechanism. Folate receptor is sorted into recycling endosomal compartment, where GPI-anchored proteins are enriched and then trafficked to perinuclear sites before eventually returning folate receptor to the cell membrane. The synthesis of a disulfide-linked folate conjugate as a reduction-responsive fluorescence resonance energy transfer (FRET) probe enabled the elucidation of

folate receptor life cycle, potential location of reduction reaction, and distinct sorting destination of cleaved yield products [55]. The disulfide disruption of folate-(BODIPY)-SS-rhodamine conjugate (folate-FRET) proceeded with a half-life of 6 h at recycling endosomal vesicle with reductive environment, which was independent of redox machinery in lysosome and Golgi apparatus. Furthermore, folate receptors (indicated by folate BODIPY fluorescent dye) were recycled back to plasma membrane, while released rhodamine was sorted into a distinct vesicle free of membrane-bound folate receptors. Since folate receptor is recycled to the plasma membrane, the timely release of the carrier-bound drug during the intracellular phase is crucial to attaining optimal intracellular drug delivery for a folate receptor-targeted system. Accordingly, folate receptor targeting drug delivery platforms with built-in reduction responsive drug unloading trigger have been formulated. In one of such systems, disulfide bond between hexaethylene glycol outer layer and cucurbit[6]uril (CB[6]) inner core was disrupted in the reducing environment of endosomes following folate receptor-mediated endocytic uptake, releasing doxorubicin entrapped within this self-assembled amphiphilic platform [56].

***11.2.3.3 Other Receptors.*** It was shown that a delivery system based on beta-cyclodextrin-containing polycations possessed strong transfection efficiency against hepatoma cell line because of asialoglycoprotein receptor-mediated uptake [57]. The protein adsorption on the surface of nanoparticles also plays a major role in nanoparticle uptake. At the initial stages of nanoparticle development, unmodified nanoparticles were prone to opsonization by RES due to the protein adsorption and subsequent uptake by Kupffer cells in the liver. On the other hand, it was reported that polysorbate 80-coated poly(butyl cyanoacrylate) nanoparticles show promising ability to cross blood–brain barrier. Follow up studies elucidated the critical role of apolipoprotein adsorption that triggers receptor-mediated endocytosis by endothelial cells lining the blood–brain barrier [58].

## 11.3 INTRACELLULAR FATE OF INTERNALIZED NANOPARTICLES

Even though it is impossible to generalize a unifying theme of intracellular fate for distinct nanoparticle systems in distinct cell types, a set of potential itinerary repetitively observed for nanoparticles could be enumerated here. Upon cellular entry, a nanoparticle starts the intracellular journey either at cytosol directly via direct membrane fusogenic entry or from within membrane-confined vesicles such as early endosomes following endocytosis and macropinocytosis. As the early endosome undergoes maturation, a fraction of cargo within the compartment could be transported and sorted either to recycling pathway or toward multivesicular body and lysosome, the most widely documented intracellular sequestration destination for nanoparticles. Meanwhile, a typical trajectory of cargo transport mediated by motor molecules along the microtubule highway towards perinuclear region could also be observed. Throughout the aforementioned endosome maturation processes, nanoparticles with specific surface properties could escape endolysosomes and enter

**FIGURE 11.2** Potential intracellular trafficking pathways for nanoparticles. MVB: multivesicular body.

cytosol at this stage, leading to either intracellular localization with or without further distribution to other subcellular organelles. Some common pathways for nanoparticle intracellular trafficking are depicted in Figure 11.2.

The intracellular fate is intimately linked with the route of entry, which is dependent on the surface properties of nanoparticles. Targeting moiety often has major influence on both entry and intracellular trafficking since endocytosis route could dictate the subsequent intracellular sorting processes. Oba et al. have demonstrated that cyclic arginine-glycine-aspartic acid (RGD) targeting peptide not only selectively boosts PEG–poly-lysine–DNA polyplex cellular entry into cells expressing $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrin receptors but also ensures preferential perinuclear localization so that transfection efficiency against HeLa cells is significantly augmented. It was shown that this was not due to enhanced uptake but due to favorable intracellular trafficking following caveolae-mediated endocytosis, which directs more plasmid DNA cargo through caveosome pathway rather than degradative lysosome pathway as suggested by Figure 11.3 [59,60].

An elegant study on the uptake and intracellular fate of gold nanoparticles in HeLa cells demonstrated the correlation between surface chemistry and cellular fate

**FIGURE 11.3** Distribution of RGD (+) and RGD (−) polyplex micelles in late endosomes and lysosomes. Polyplex micelles loading Cy5-labeled pDNA (red) were incubated with HeLa cells for 1 h. After replacement with fresh medium, the cells were reincubated for 11 h. The cell nuclei were stained with Hoechst 33342 (blue), and the acidic late endosomes and lysosomes were stained with LysoTracker Green (green). (a) CLSM images of the cells transfected with RGD (−) micelles (left) and RGD (+) micelles (right). The scale bars represent 20 μm. (b) Quantification of Cy5-labeled pDNA colocalized with LysoTracker Green in the inner cytoplasm. Error bars in the graph represent SEM ($n = 10$). (*Source:* Reprinted with permission from Reference [60]. Copyright (2008) American Chemical Society.)

of gold nanoparticles. Bare gold nanoparticles were taken up by endocytosis and were confined exclusively in endosomes, while PEGylation prevented cellular uptake completely. However, the inclusion of these PEGylated gold nanoparticles within liposomes or functionalization with cell penetrating peptide resulted in cytosolic distribution, circumventing the endosomal fate of unmodified counterpart as demonstrated in Figure 11.4 [61]. The cytosolic disposition was attributed to direct entry of nanoparticles across the cell membrane and/or disruptive surface property that damaged endosomal membranes [61].

### 11.3.1 Organelle Targeting

Specific organelle targeting is an important determinant of nucleic acid delivery efficiency of nonviral systems. RNA interference occurs in the cytosol while DNA transfection can only be achieved following transport of plasmid DNA into the nucleus. For successful siRNA delivery into cytosol, nanocarriers that enter the cell through endocytosis must exhibit endosomal escape [62,63]. For successful gene

**FIGURE 11.4** Uptake of PEG-modified gold nanoparticles in the presence of liposomes. Observed uptake mechanisms without apparent direct involvement of the liposomes include (a) caveolae and (b) clathrin-mediated endocytosis. Particle delivery by liposomes and subsequent uptake are shown in (c) and (d). Perhaps reflecting the wealth of different uptake mechanisms available under these conditions, nanoparticles (free) are found in the endosome (e) or free in the cytosol (f). Scale bars are 200 nm. (*Source:* Reprinted with permission from Reference [61]. Copyright (2008) American Chemical Society.)

delivery, nanocarriers must achieve nuclear entry after endosomal escape so that the genetic materials are delivered directly into the nucleus. To this end, nuclear localization signal (NLS) peptide has been utilized to enable nuclear targeting. Two different targeting ligands may be conjugated to the same nanoparticle surface to achieve sequential cell and organelle targeting. For example, conjugation with RGD and NLS peptides imparted both tumor targeting and nucleus targeting property to 30 nm gold nanoparticles [64].

Mitochondria serve as the powerhouse of the cell, producing ATP through oxidative phosphorylation. In addition, mitochondria contain a distinct set of DNA inherited from maternal source. Abnormal functionality in mitochondria has been linked with a diverse range of neurodegenerative disorders including Alzheimer's. Thus, a mitochondria-targeted delivery system is desirable for mitochondrial gene therapy, metabolic diseases, and proapoptotic strategy for cancer treatment. Lipid nanoparticles loaded with proapoptotic drug SV30, in spite of lacking a specific mitochondria targeting functionality, exhibited a preferential accumulation at sites adjacent to mitochondria, as suggested by colocalization of MitoTracker (a mitochondrion labeling fluorescent dye) and Nile red-labeled lipid nanoparticles [65]. On the other hand, liposomes functionalized with mitochondriotropic triphenylphosphonium cations promoted preferential localization of nanocarrier at mitochondria and improved the therapeutic efficacy of ceramide both *in vitro* and *in vivo* [66]. A multifunctional iron oxide "nanoworm" functionalized with both glioblastoma targeting peptide (CGKRK) and mitochondria targeting peptide ($_{D}$[KLAKLAK]$_2$) has shown promising efficacy in treating glioblastoma bearing mice by inducing proapoptotic processes. Neither tumor targeting peptide nor mitochondria targeting peptide alone could confer this beneficial activity, highlighting that the sequential, cooperative action of both peptides was indispensable to achieving intracellular delivery followed by modulation of intracellular trafficking and localization [67].

### 11.3.2 Exocytosis of Nanoparticles

The story of nanoparticle–cell interaction would be incomplete without a discussion of the elimination mechanisms of nanoparticles, which has important bearing on nanoparticles' retention, drug release profile, and toxicity. In addition to the possible disassembly and degradation of nanoparticles in the lysosomes, exocytosis is another clearance mechanism for internalized nanoparticles. Cargo that has been sorted to secretory/recycling vesicles is destined to the fate of exocytosis. The relatively scarce data on exocytosis of nanoparticles prevent generalization of rules governing nanoparticle excretion. Nevertheless, according to the studies on nanoparticle internalization and sorting, it is conceivable that for a specific nanoparticle of interest (with unique size, shape, and surface property) whether or not exocytosis occurs at all, to what extent, and how fast likely depends on the cell line under study and could be highly context dependent.

Even though the data with regard to exocytosis are not as abundant as internalization, exocytosis of poly(D,L-lactide-*co*-glycolide) nanoparticles has been studied *in vitro* using human arterial vascular smooth muscle cells (VSMCs). These studies showed that intracellular concentration of nanoparticles was maintained as long as the cells were in contact with excess nanoparticles. Once the extracellular nanoparticle concentration gradient was removed, exocytosis of nanoparticles occurred with about 65% of the internalized fraction undergoing exocytosis in 30 min [68]. Energy depletion reduced exocytosis, indicating the ATP-dependent nature of this active sorting process. In addition, protein adsorption on nanoparticle surface has a major influence on sorting of nanoparticles into

exocytic pathway as exocytosis was abrogated in serum-free culture medium. Slowing et al. have elegantly shown that when two separately cultured flasks of human umbilical vein endothelial cell (HUVECs) incubated with either FITC-labeled mesoporous silica nanoparticles or TRITC-labeled nanoparticles were pooled, individual cells contained both FITC- and TRITC-labeled nanoparticles, providing indirect evidence that internalized mesoporous silicon nanoparticles could undergo exocytosis by HUVEC, leading to reuptake and exchanging of expelled nanoparticles [69]. However, no such effect was observed in the HeLa cell line. In another experiment, about 50% of internalized D-penicillamine-coated zwitterionic quantum dots (DPA–QDs) of 4 nm radius was expelled by HeLa cells. The exocytosed fraction increased with a half-life of 21 min and reached saturation after 2 h [70]. Similar to quantum dots, nanodiamonds made of nanocarbon allotrope with negatively charged nitrogen defects as fluorescent centers have good photostability and therefore are candidates for long-term labeling of stem cells. Retention rate is an important parameter to consider before using fluorescent nanodiamonds to track a specific cell of interest. There was little (~15% or less) excretion of the endocytosed nanodiamond after 6 days of labeling from both HeLa and 489-2.1 cells, but exocytosis occurred more readily (up to 30%) for 3T3-L1 preadipocytes [71]. On the contrary, addition of silver nanoparticles at a concentration of 50 μg/ml to RBL-2H3 mast cell line triggered degranulation instantaneously [72]. Decisive *in vivo* and mechanistic experiments investigating exocytosis of nanoparticles are lacking. It remains to be seen whether exocytosis patterns seen *in vitro* would be observed *in vivo* and whether exocytosis has any major implications for nanoparticle pharmacokinetics and pharmacodynamics.

## 11.4 IN-DEPTH ELUCIDATION OF INTRACELLULAR TRAFFICKING EVENTS ENTAILS HIGH RESOLUTION IMAGING TECHNIQUES

The advent and application of more advanced imaging techniques will enable in-depth understanding of the intracellular trafficking events. Spinning disk confocal microscopy has increasingly become the method of choice for live cell imaging due to its quick data acquisition compared to more widely available conventional confocal instrumentation. In conjunction with short-term overexpression of fluorescently tagged Rab family proteins by transfection, the intracellular trafficking of 40 nm fluorescent polystyrene nanoparticles in HeLa cells has been observed with high spatial and temporal resolution [73]. The fraction of nanoparticles co-localized with Rab5, a marker for early endosome, decreased over time, while the fraction of nanoparticles co-localized with Rab7/9, markers for late endosome, increased correspondingly until reaching a plateau of 80%, which was consistent with the data achieved by using LAMP1 as the lysosome marker. Only miniscule co-localization of nanoparticles with Rab11 was observed, suggesting that nanoparticle trafficking into recycling vesicles was not a major sorting route in this experimental setup.

The resolution of conventional optical microscopy, including fluorescent confocal microscopy, is diffraction limited. For most studies, the resolving power of the

conventional techniques cannot surpass the limit of 200–300 nm, depending on the instrumentation and fluorescent emission wavelength under study. However, the diameter of most nanoparticles employed in current research is below this diffraction-limited resolution. Conceivably, as researchers gain access to more advanced imaging techniques, such as super-resolution microscopy capable of generating subdiffraction limit resolution, our understanding of nanoparticle intracellular trafficking and fate can progress dramatically. It was reported that two 40 nm nanoparticles separated by an 85 nm center-to-center distance could be resolved by stimulated emission depletion (STED) microscopy, a scenario unresolvable by diffraction-limited conventional confocal microscopy [74]. The uptake and aggregation of silica nanoparticle with 128 nm diameter in lung carcinoma cell line A549 have also been visualized by STED microscopy [75]. Another report shows that 32 nm silica nanoparticle could gain access to nucleus and form aggregates within nucleus progressively. In contrast, 80 nm silica nanoparticles not only migrate at a slower rate intracellularly but also fail to penetrate nuclear membrane [76]. This report also demonstrated the unique strength of super-resolution technique in imaging intracellular fate of nanoparticles.

## 11.5 FUTURE PERSPECTIVES

Nanoparticulate systems hold great promise in enhancing the therapeutic efficacy of drugs with intracellular sites of action [77] and improving the efficacy of nucleic acid-based therapies encompassing siRNA and gene delivery [78]. The last decade has witnessed tremendous advancement of our understanding of cellular entry and intracellular trafficking of nanoparticles. This progress could guide the rational design of next generation of nanoparticles with improved therapeutic efficacy. However, one limitation in the field has been the understandable lack of consistency across research groups in the cell and animal models used. Nanoparticle–cell interaction is highly dependent on the cell line and treatment conditions used. For example, it has been shown that even closely related cell lines such as PC3, PC3-flu, and PC3-PSMA (the latter two were derived from the former) demonstrate dramatically differential interaction profiles with quantum dots. In PC3 cells, punctate cytoplasmic localization was observed, while in PC-PSMA cell line, co-localization of nanoparticles with transferrin was observed at the perinuclear recycling compartment [79]. The preferential sequestration of DNA polyplexes in perinuclear microtubule organizing compartment (MTOC) of PC3-PSMA cells (similar to that seen with quantum dots) was associated with the poor transfection efficiency. In contrast, the cytoplasmic localization of DNA polyplexes in PC3 cells resulted in relatively higher transfection efficiency [80]. Thus, caution should be exercised when reaching broad conclusions from a specific experimental setup and extrapolating observations from an experiment done with one cancer cell type to another cancer cell type or worse, to noncancerous cells and professional phagocytes.

From a therapeutic perspective, heterogeneity in tumor cell–nanoparticle interaction within a given population of tumor cells could pose significant problems. Differences in uptake of cytotoxin-armed nanoparticles within a given population

could result in differential cytotoxicity in the population and impose a selection pressure that could result in the enrichment of drug-resistant clones. Thus, in the context of clinical applications, future nanoparticle design may have to consider nanoparticles' interaction with the entire tumor cell population as well as a whole gamut of other tumor-associated cell types (tumor-associated macrophages, endothelial cells, mesenchymal stem cells, to name a few) *in vivo*. This would require a "systems biology" approach to better understand the complex interactions that nanocarriers likely have with biological systems.

## 12.1 INTRODUCTION

The rapid evolution of nanotechnology has led to the realization of nanomedicine, defined as the use of engineered nanostructures for molecular level monitoring, repair, construction, and control of human biological systems [1]. Projections indicate that the nano pharmaceutical market will reach US$180 billion by 2015 [2]. Nanomedicine has originally focused on drug delivery and the treatment of cancer; however, new applications are emerging such as vaccine adjuvants, medical imaging, and gene therapy, the latter being applicable to a wide range of therapies ranging from Parkinson's disease treatment to osteogenesis [3]. The potential of nanotechnology to improve medicine is not limited to the use as a vehicle for medicines but also applicable for streamline discovery, design, development, and production of medications. These advances may reduce the time it takes to move a medicine from the bench to the clinic (currently 8–14 years) and the cost (current average of US$1.8 billion) [4]. On the other hand, the abundant use of and exposure to nanomaterials naturally raises

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*,
Edited by Shayne C. Gad

the concern of potential toxicity. However, limited data are available regarding toxicological evaluation of these new nanoconstructs, despite the accelerating rate of research papers describing new nanomaterials. The situation is similar regarding the investments in the emerging nanotechnology. For example, only 6.6% of the investment of the U.S. government in nanotechnologies is being spent on investigating the health and environmental consequences of their use [5].

In the United States, nanomaterials may, at the discretion of regulatory bodies, be deemed to fall under regulations pertaining to laws such as the toxic substances control act, while in the European Union they may fall under the regulation of the Registration, Evaluation, and Authorization of Chemicals Act [6]. Nanomedicine approval by regulatory bodies is subject to the standard preclinical, clinical, and postrelease regulations of traditional drugs. The majority of current nanomaterial regulation outlines are based on regulations developed for standard materials [7]. Early experimental studies to assess the toxicity of nanoparticles (NPs) rely on knowledge obtained from the studies on the nuisance of metal fumes, exposure to asbestos, synthetic fibers, silica, and dust. However, the increasing diversity of engineered nanomaterials such as metals, dendrimers, chitosan, silica, carbon nanotubes, and others used for medical applications have resulted in the need for improved methodologies to evaluate the safety of these new nanoconstructs [8]. Standard tests to evaluate toxicity are not always applicable to nanomedicine. For example, carbon nanotubes (CNTs) have been shown to cause a false cytotoxic effect in the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay, and titanium NPs (TiNPs) bind lactic dehydrogenase (LDH) to interfere with LDH assays [9–11]. A glaring example of the shortcomings of classical toxicological evaluation is dose measurements. Traditional mg/kg dose measurements still need to be investigated for comparison with other medicines and poisons. However, for the purposes of having meaningful measurements of the toxicity of nanomedicine, surface area should be considered as the most important determinant of reactivity and hence possible toxic interaction with biological systems. A battery of other characteristics such as shape, size, charge, and porosity are as important as surface area. Currently there is no satisfactory standard or consensus on how to define nanomedicine exposure and assess their toxicity. As shown in Table 12.1, most of the toxic attributes of a nanomedicine are governed by the physicochemical parameters of the nanoconstructs. Complete understanding of these parameters is essential for the prediction of a specific nanomedicines safety. Section 12.2 is a summary of the current knowledge on safety of commonly used nanoconstructs in medicine, followed by our recommendations for conducting safety studies for novel nanomedicines.

## 12.2 SAFETY OF COMMONLY USED NANOCONSTRUCTS IN NANOMEDICINE

### 12.2.1 Liposomes

Liposomes are widely used for drug and gene delivery [46,47]. Several types have been approved by the Food and Drug Administration (FDA) for clinical use [48] such

**TABLE 12.1 Description of the Administration Routes, Characteristics Affecting the Biodistribution and Molecular Effects of Various Types of Nanoparticles**

| | Liposome | Polymeric Micelle | Metal Nanospheres and Nanorods | Carbon | Dendrimers | Silica Nanoparticles |
|---|---|---|---|---|---|---|

as Doxil, Danuxome, Myocet, Depocyt, and MEPACT [49–53]. Several studies have demonstrated that liposomes accumulate in organs such as the liver and spleen and are consumed by macrophages making these tissues susceptible to toxicity (Figure 12.1) [54]. Excessive liposome deposition in macrophages may affect their phagocytic capacity or alter their gene expression. Several *in vitro* experiments have shown that liposomes may downregulate the production of nitric oxide and tumor necrosis factor (TNF)-α by macrophages and may cause macrophage cell death [55]. However, there is no scientific evidence that therapeutic doses of various liposomes can induce clinically relevant immunosuppressive effects [56].

Depending on their composition, liposomes have also been observed to stimulate the innate immune responses [56]. Doxil, a polyethylene glycol (PEG)-grafted liposomal carrier for doxorubicin, has been shown to promote allergic reactions, despite the view of PEG as immunologically inert [57]. In the central nervous system (CNS) of rats, liposome administration has been observed to cause focal astrogliosis, extracellular edema, and inflammation [34]. The dependence of liposome toxicity on

**FIGURE 12.1** Schematic representation of the toxicity associated with specific nanomedicines on human organs.

their composition has been documented both *in vitro* [58] and *in vivo* [59]. Lecithin–cholesterol–dicetyl phosphate or lecithin–cholesterol–stearylamine administered intracerebrally to mice produced neuronal edema and/or necrosis, generalized epileptic seizures and death due to respiratory failure immediately after injection, whereas lecithin–cholesterol–phosphatidic acid liposomes produced relatively little effect [59].

### 12.2.2 Polymer Conjugates and Polymeric Micelles

Biodegradable polymers including poly(D,L-lactic acid) and poly(D,L-lactic-*co*-glycolic acid) have been commonly used to structure NPs and encapsulate a high load of poorly soluble material [60]. Since the approval of the first polymeric conjugates, PEG conjugated adenosine deaminase (ADA) [61] and styrene maleic acid conjugated neocarzinostatin polymer (SMANCS), for cancer treatment in the early 1990s, the field of polymer-based nanomedicine has grown exponentially [35,36]. Synthetic polymers such as *N*-(2-hydroxypropyl) methacrylamide (HPMA) copolymers, poly (ethyleneimine) (PEI), divinyl ether and maleic anhydride (DIVEMA), poly(vinylpyrrolidone) (PVP), PEG, and linear polyamidoamines as well as pseudosynthetic polymers such as poly(amino acids), and natural polymers including dextran, dextrin, hyaluronic acid, and chitosans have been used at a clinical level as a polymeric platform for drug delivery [62].

A major drawback of the use of polymeric carriers is related to their rapid uptake and accumulation by the reticuloendothelial system (RES) located in the liver, spleen, and lung [63] (Figure 12.1), which reduce the dose that can reach the tumors and raise concerns of chronic toxicity in these organs [64]. An example is HPMA copolymers that accumulate in RES organs in a size-dependent manner [65]. Furthermore, polymers can influence the biological responses. For example, SMANCS and DIVEMA caused increased secretion of interferon-γ and -β and increased the activity of natural killer and cytotoxic T-lymphocyte cells [66–69]. Another aspect limiting the use of certain polymers is their degradation profile, essentially HPMA and PEG copolymers which are nonbiodegradable, a parameter essential to consider for nanomedicine development [70].

### 12.2.3 Dendrimers

Dendrimers have gained a lot of interest over the last few years as drug carriers because of their well-defined polymeric structure, low polydispersity index (PDI), and functionalized surface diversity. In 1985, Tomalia et al. described the synthesis of polyamidoamine (PAMAM) dendrimers [71], and subsequently an array of dendrimers has been synthesized utilizing Tomalia's principles. More recently, on the basis of their ability to disrupt protein aggregates, dendrimers have been studied for the treatment of prion diseases and neurodegenerative diseases and as an antiviral agent for the treatment of AIDS [72].

To date, only two dendrimers have reached clinical development. These are the contrast agent Gadomer®, which is in Phase II clinical trial for the delineation of

microvascular obstruction regions [73], and the intravaginal topical virucidal agent VivaGel® in Phase I clinical trial [74]. The complexity of obtaining chemically pure dendrimers is a major challenge for clinical development. Moreover, PAMAM dendrimers showed a distinct *in vivo* toxicity profile depending on the functional groups on their surface. Amine-terminated PAMAM dendrimers showed higher toxicity than carboxyl- or hydroxyl-terminated PAMAM dendrimers. Amine-terminated dendrimers triggered fatal hemotoxicity manifested as disseminated intravascular coagulation-like condition (DIC) and hemolysis.

### 12.2.4 Carbon Nanotubes

Carbon-based nanomaterials are used either as hollow spheres, ellipsoids or cylinders. Spheres and ellipsoids are referred to as fullerenes while cylinders are categorized as nanotubes. Fullerenes, especially C60, have exhibited some promise for drug delivery and for antiviral treatment as photosensitizers [75]. Pristine CNT and C60 are highly hydrophobic, chemically inert, and insoluble. Various biological and bioactive molecules such as proteins, enzymes, vaccines, DNA, and siRNA have been attached to CNTs and used for different biomedical applications [76]. More recently, CNT's photothermal properties have been exploited for their effect on cancer ablation [77]. CNTs exist in different forms such as single wall nanotubes (SWNT) and multiwalled nanotubes (MWNT), which can both be chemically modified and/or functionalized with bioactive molecules to enhance their solubility and drug targeting [78].

However, there is a growing concern on the use of fullerene and CNTs on the basis of *in vitro* and *in vivo* animal studies (Figure 12.1). For example, incubation of keratinocytes and bronchial epithelial cells with SWNTs has been shown to cause oxidative stress and generation of reactive oxygen species (ROS) [79]. Other reports described the oxidative stress and production of ROS following treatment by CNTs on macrophages and other cell lines, either be due to metal impurities [80] or as a result of the experimental conditions [81].

Acute and subacute toxicity studies of fullerenes by intraperitoneal injection in rats determined an approximate $LD_{50}$ of 600 mg/kg with kidney impairment often observed in deceased animals [82]. There was no mortality in an acute oral and skin toxicity test [82]. Lipid peroxidation in the brain of largemouth bass was observed after 48 h exposure to 0.5 ppm of soluble fullerene C60 [83]; although these effects were later found to be associated with impurities from the solvent used for the preparation of soluble fullerene [84], pure soluble fullerene showed antioxidant activity [84]. Soluble fullerene modified with two cationic chains (fulleropyrrolidine derivatives) triggered hemolysis and appeared cytotoxic to a variety of cell lines at concentration between 20 and 60 μM [85]. Several studies have looked at the potential effects of fullerene on embryonic development. For example, intraperitoneal injection of 50 mg/kg CNTs to pregnant rats (11 days gestation) with fullerene C60 solubilized with polyvinyl pyrrolidone was shown to cross the placental barrier and distribute into embryonic tissues, causing the death of the embryo as a consequence of several anomalies and malformations [86].

CNTs bear remarkable structural similarities to the carcinogenic asbestos fibers and have been shown to induce asbestos-like inflammation and foreign body granulomas in mice [87]. Pulmonary exposure of rodents to CNTs has been shown to induce inflammation and granuloma formation but evidence that these granulomas progress to mesotheliomas is yet to be found [88,89]. Pulmonary exposure to fullerene in rodents has also shown to induce lung inflammation, fibrosis, and DNA damage [90,91]. Exposure of adult male rats to 200 μg of CNTs has been observed to cause decreased sperm production [92]. One major concern for the application of fullerenes and CNTs in biomedicine is the lack of consistent data regarding the effect of functionalized particles and impurities associated with their synthesis on the biological environment. All of these parameters fundamentally contribute to the difference in biological responses observed across the different studies.

### 12.2.5 Silica NPs

Mesoporous silica NPs (MSNs) have a well-defined structure that can be functionalized with a wide range of organic functional groups [93]. In recent years, MSNs have been investigated for biomedical applications such as biosensors, enzyme immobilization, detection of cancer cells *in vivo*, targeted cancer therapy, DNA delivery, and drug delivery [94–99]. Recently, the FDA approved the first human clinical trial of Cornell dots, multimodal silica NPs that enclose several dye molecules to be used for the detection of cancer cells [100].

There are a few studies investigating toxic effects of MSNs. Studies determine that the cytotoxicity of MSNs depends on the shape and size and functionalized surface type [101]. Size-dependent cytotoxicity is well documented with smaller particles generally being more cytotoxic. For example, MSNs with an identical geometry can trigger a size-dependent necrosis in human endothelial cells *in vitro* [102]. Although subcutaneously injected MSNs did not show toxicity, intraperitoneal and intravenous injection of nonfunctionalized MSNs with sizes varying from 150 to 4000 nm, have been shown to be lethal in mice [103]. The effect is partially based on the hydrodynamic sizes of $SiO_2$ postprotein exposure in relation with the physicochemical characteristics of $SiO_2$ NPs and the vasculature which further promoted multiple organ failures [104]. This toxicity appears to result from the particles themselves and not from contaminants or degradation products [103]. MSN was also shown to increase hemolysis at concentrations above 100 μg/ml, an effect influenced by the surface area and the geometry of the MSNs [105]. Furthermore, silica NPs were shown to enhance thrombus formation following intratracheal instillation or intravenous injection in a hamster model of thrombosis [106]. Intravenous injection of MSNs has been found to induce liver injury such as inflammation, silicotic nodular-like lesions, fibrosis, Kupffer cell activation, and the development of oxidative stress-associated liver damage at high doses (50 mg/kg) in mice [45]. Altered biliary function and glomerular function have also been observed in mice following 20 mg/kg MSNs intravenous injection [107]. MSNs have been shown to cross the blood–brain barrier (BBB) and accumulate in the striatum, where they deplete dopamine and induce oxidative stress and inflammation, and to damage the murine placenta and enter the fetal brain [43,108].

### 12.2.6 Metal-Based NPs

Metal-based NPs such as aluminum, gold, silver, iron, zinc, and titanium are currently being developed as nanomedicines; however, their unique properties make it difficult to predict their toxicity. Several studies were conducted *in vitro* and *in vivo* to demonstrate the influence of intrinsic parameters such as size and shape on their adverse toxicological effects. Figure 12.2 summarizes the physicochemical properties of the different nanomedicines that may influence biocompatibility and the possible pathways involved in their toxicity.

Aluminum (Al) is currently utilized for medical applications such as antacids, buffered aspirin, and vaccine adjuvants [109]. Al has no known biological function but has been demonstrated to cause significant toxicity such as dialysis encephalopathy, osteomalacia, and microcytic anemia [110]. The role of Al in dialysis encephalopathy is of particular concern and has been recognized in humans as early as 1979 when its ability to pass through the BBB and accumulate in the CNS to cause dementia was first reported in patients on chronic hemodialysis [111]. Of the various forms of dementia thought to be related to Al exposure, Alzheimer's disease has since been the most intensely studied [112]. Despite this research as well as observations of increased Al in the brains of Alzheimer patients and its ability to enhance amyloid beta penetration [113,114], there is no concrete evidence for the causality and this topic is still controversial [115].

**FIGURE 12.2** Physicochemical properties of nanomedicines that may influence biocompatibility. (a) Illustration of the importance of the nanomaterial composition, surface coating, solubility, degradation, dissolution, and contaminants with biological tissue. (b) Possible mechanistic pathway for toxicity induced by exposure to nanomedicines. Nanomedicines may degrade rapidly outside the cells or following endocytosis. The resulting fragments or contaminants may target mitochondria and promote oxidative stress due to the increased production of ROS. The ROS and the nanoparticles fragments or contaminants trigger downstream signaling responses that promote genotoxicity. ROS, reactive oxygen species.

Gold NPs (Au NPs) have been extensively studied for use in nanomedicine. Colloidal gold has been used since the 1920s for the treatment of tuberculosis before the emergence of antibiotics and has recently found some applications for the treatment of rheumatic disease [116]. More recently, Au NPs have been investigated for photothermal therapy, imaging, gene therapy, and drug delivery [117–120]. Biodistribution studies of Au NPs indicate that they preferentially accumulate in the liver, spleen, kidney, and lungs in a size-dependent manner with smaller particles (<50 nm) showing dispersion throughout all tissues [121]. Several studies have examined the effect of Au NP size on toxicity and have demonstrated that nanoclusters of 1.4 nm exhibit a higher cytotoxicity compared to nanoclusters of 15 nm [122]. Animal studies have also demonstrated that Au NPs can cause damage to the liver, cardiovascular system, and immune system [123,124] in a size-dependent manner. Additional studies have determined the influence of the charge, shape, and surfactant used for synthesis of the Au NPs on the potential cytotoxicity [122].

Metal-based NPs have also been demonstrated to induce oxidative stress following administration. Iron (Fe) NPs are being developed for use in magnetic resonance imaging, photothermal therapy, tissue repair, and drug delivery. The Fe NP Feraheme was approved in 2009 for the treatment of iron deficiency [125,126]. Oxidative stress is consistently observed following Fe NP treatment [125,127,128] and is highly concerning due to its potential implication in a variety of diseases including neurodegenerative diseases, cardiovascular diseases, and cancer [129–131]. This oxidative stress is also likely to be the cause of the Fe NP-induced genotoxicity [132,133]. The enhanced permeability observed *in vitro* at 50 μg/ml and the enhanced microvasculature permeability observed *in vivo* at 0.8 mg/kg [134,135] indicate that Fe NPs may play a role in the development of cardiovascular diseases, which is supported by the observation of Fe NPs in human atherosclerotic plaques [130,136]. Silver (Ag) NPs have been shown to cross the BBB and trigger oxidative stress in the CNS and impair short-term memory [137,138]. Titanium (Ti) NPs and zinc (Zn) NPs have also been shown to be associated with CNS toxicity and impairment of the spatial recognition and memory [139–141].

## 12.3 EVALUATION OF NANOMATERIAL TOXICITY

A classical scheme for toxicity assessment is represented in Figure 12.3. In Section 12.3.1, we briefly summarize the principles of toxicological assessment of nanomaterials. Toxicity assessments are classified into acute, subacute, subchronic, and chronic studies. Absorption, distribution, metabolism, excretion, and pharmacokinetics (ADME/PK), carcinogenic, and teratogenic studies are also required for complete evaluation of nanomaterial toxicity.

### 12.3.1 Characterization

Thorough and systematic physicochemical characterization of materials is essential prior to studying their toxic effects *in vivo*. One of the main reasons is to ensure the

**FIGURE 12.3** Proposed paradigm for toxicity testing of nanomedicines.

accuracy and reproducibility of the observed toxic effects of the studied NPs. Toxicity of NPs is significantly influenced by their physicochemical properties such as size, shape, surface charge, charge density, composition, density of structure, presence of pores, and surface activating sites. Hence, documentation of the characteristics of the NP under evaluation becomes crucial in order to correlate with the observed biological effects *in vivo*. Characterization data are important to facilitate comparison of toxicity results of a given NP with other nanoconstructs. Instrumentation techniques have advanced considerably in the past decades to sufficiently characterize the physicochemical properties of NPs, including dynamic light scattering techniques for size determination, zeta potential measurements for relative particle charge, electron microscopy (scanning and transmission) to qualitatively analyze the size and shape, nuclear magnetic resonance to accurately determine chemical structures, X-ray photoelectron spectroscopy to measure chemical compositions and chemical and electronic states, mass spectrometry for mass and elemental analysis and spectroscopy techniques that measure absorption, emission, or scattering of either wavelength or frequency for the determination

of the size and distribution. An important note of caution while characterizing nanomaterials is to evaluate these properties under physiologically relevant conditions.

### 12.3.2 Absorption, Distribution, Metabolism, and Excretion (ADME)

Understanding the pharmacokinetics of NPs is an integral part of assessing their toxicity as it can facilitate an in-depth understanding of nanomaterial behavior in a biological system and provide valuable information which serves as a prelude to Phase I clinical study in humans. ADME studies are performed in at least one rodent species and one nonrodent species. In humans, ADME studies (usually a Phase I clinical trial) are performed in 8–10 healthy male subjects, unless the drug in question is a cytotoxic cancer treatment which is studied in patients instead of healthy volunteers [142]. The route of administration should be the proposed route for clinical application and usually a single dose is sufficient [142].

Absorption studies investigate the systemic exposure relative to the route of administration. *In vitro* absorption studies can be used to estimate *in vivo* absorption such as the Caco-2 cell monolayer to estimate intestinal absorption or a human skin equivalent model for dermal absorption [143,144]. *In vivo* oral absorption is usually investigated in a rodent model, where the plasma concentration is measured at certain time points following oral administration [145]. Microscopy methods such as scanning electron microscopy and multiphoton microscopy can be used to determine dermal NP absorption *in vivo* [146]. The *in vivo* whole body distribution of a radiolabeled nanomedicine may be quantitatively evaluated using whole body autoradiography or inductively coupled plasma mass spectroscopy [147,148]. At specified intervals, plasma samples may be taken to determine multiple pharmacokinetic parameters such as $T_{1/2}$, $C_{max}$, AUC, $T_{max}$ and $V_d$ [142]. It is critical that the radiolabel/fluorophore does not dissociate from the nanomedicine during metabolism and does not interfere with the activity of the nanomedicine, its metabolism, and/or stability [142]. The hepatic microsome test investigates potential metabolism of nanomedicines by the enzymes of the smooth endoplasmic reticulum (SER), for example, CYP450 enzymes and glucuronosyltransferases. Studies utilizing isolated hepatocytes are also conducted as these retain SER, cytosolic, and mitochondrial enzymes which may also metabolize the nanomedicine [149,150]. Excreted metabolites may be identified to determine the likely metabolic pathways *in vivo* such as hydroxylation, glucuronidation, sulfation, and methylation [142]. Following the dosing, urine, fecal, and bile samples are obtained at specified intervals to study the excretion mechanism of the nanomedicine (for more information consult [142]).

### 12.3.3 Acute and Chronic Toxicity

Acute and subacute toxicity studies (Table 12.2) may be measured based on a single or repeated dose administration via various methods of administration such as intravenous, oral (one dose per day), dermal, or inhalation. Typically, acute toxicity studies require five animals/sex/dose to be monitored over a period of ~14 days with

**TABLE 12.2 *In Vitro* and *In Vivo* Assays to Evaluate the Potential Toxic Effect of Nanomedicines**

| Toxicity | *In Vitro* | *In Vivo* |
|---|---|---|
| Genotoxicity | Ames test<br>Comet test | Micronuclei test<br>Unscheduled DNA test |
| Carcinogenicity | Ames test<br>Comet test<br>Syrian hamster embryo assay<br>Immortalized aneuploid mouse cell assay | Two-year rodent cancer bioassay |
| Reproductive toxicity | Mouse morula assay<br>Mouse blastocyst assay<br>Sperm viability assay | One generation rodent reproductive toxicity study<br>Two generation rodent reproductive toxicity study<br>Prenatal development toxicity study |
| Acute and subacute toxicity | — | Rodent acute and subacute toxicity studies<br>Dog acute and subacute toxicity studies<br>Primate acute and subacute toxicity studies |
| Chronic and subchronic toxicity | — | Rodent chronic and subchronic toxicity studies<br>Primate chronic and subchronic toxicity studies |

outcomes of interest being weight change, response to the dose, function of organ systems, mortality, clinical pathology, and gross necropsy [151]. For subacute studies, 10 rodents/sex/dose are monitored over 4–5 weeks. Subchronic and chronic studies measure the effects of chronic dosing and exposure over the majority of the lifespan of the animal. Subchronic studies span ~13 weeks while chronic studies span 18–30 months. Subchronic and chronic studies measure the same outcomes as acute studies with the addition of ocular toxicity, cardiovascular function, neurotoxicity, and immunotoxicity [151].

### 12.3.4 Genotoxicity

Genotoxicity is a vital test (see Table 12.2) for any new medication as it is an important indicator of the potential for the medication to induce teratogenic or carcinogenic effects. The most common *in vitro* tests are the Ames test and the comet test. The Ames involves histidine-dependent cell lines of *Salmonella typhimurium,* which are unable to grow on histidine-deficient media. If the bacteria are able to grow on the media following incubation with the nanomedicine in significantly higher numbers than the control, it is likely that the material is mutagenic [152]. The comet

test involves mammalian cells, usually lymphocytes, being exposed to the material and then lysed, their genetic material extracted and then run on an electrophoresis gel. Broken DNA unwinds and so is unable to move through the gels with the same speed as intact DNA, resulting in a dense ball of intact DNA with a spread of DNA following in a pattern much similar to the tail of a comet [153].

The *in vivo* tests commonly performed are the micronuclei test and the unscheduled DNA synthesis test. The micronuclei test is reliable and well validated. The premise is that, as an erythroblast develops into an erythrocyte, the nucleus of the cell is excised but the micronuclei (a signal of incorrect chromosome distribution during anaphase) may be left behind; therefore, the presence of a significantly larger number of micronuclei than the negative control signals genotoxicity of the material [154]. The unscheduled DNA synthesis test measures DNA synthesis in mammalian liver cells that are not undergoing S phase scheduled DNA synthesis. DNA synthesis that is not scheduled is assumed to be a result of DNA repair following damage by the compound being investigated [155].

### 12.3.5 Carcinogenicity

Carcinogenicity is a serious concern for any medication. It may occur via two main mechanisms known as genotoxic and nongenotoxic carcinogenicity with genotoxic carcinogens being up to 50 times more potent than nongenotoxic carcinogens [156]. Nongenotoxic carcinogens have their effect via disruption of cellular metabolic processes and signaling pathways. Nongenotoxic carcinogens may, for example, alter the production of hormones that regulate the cellular mitotic rate (17β-estradiol), act as immunosuppressant (cyclosporin) or induce tissue-specific toxicity and inflammatory responses (arsenic) [157].

*In vitro* carcinogenicity tests (see Table 12.2) generally involve much of the same genotoxicity tests as above but also involve cell transformation assays using Syrian hamster embryo cell lines and immortalized aneuploid mouse cell lines [158]. The Syrian hamster embryo cell test is often used and signals carcinogenicity of a substance via morphological transformation of cell cultures [158]. The immortalized aneuploid mouse cell lines signals carcinogenicity via a progression from immortality to tumorigenicity [158]. The two-year cancer bioassay in rodents is considered the gold standard of carcinogenicity tests as it monitors the rodent for the greater portion of their lifespan. This test usually requires at least three different dose groups with at least 50 animals/sex/dose. The dose is administered daily for 24 months during which time tumor development, time of tumor onset, tumor location, dimensions, appearance, and progression are closely monitored [159].

### 12.3.6 Reproductive and Developmental Toxicity

Reproductive toxicity studies are necessary to gauge the possible effects of nanomedicine on reproductive ability and teratogenicity. Although some teratogenic effects are a consequence of genotoxicity, some are nongenotoxic such as retinoic

acid. *In vitro* studies to evaluate possible reproductive and developmental toxicity include studies of sperm viability and murine embryos (Table 12.2). The evaluation of various parameters of sperm health including motility [160], apoptosis and necrosis, mitochondrial function, and LDH leakage [161] following incubation with the nanomedicines may also be informative. The effects of the nanomedicine in question on the development and proliferation of mouse morulas and blastocysts may also be studied *in vitro* to identify the effects of the nanomedicines on the viability and health of the embryo [162]. A one-generation *in vivo* study involves both males and females [163]. Sufficient numbers of animals are used in order to give 20 litters (assuming sterility is not an issue). The compound of interest is administered to the animals, males 2 weeks prior to, during, and after mating and females for 54 days to allow for 14 days premating, 14 days mating, 22 days gestation, and 4 days lactation. The parameters are pregnancy duration, stillbirths, live births, and litter number, size, sex, and abnormalities. Gross necropsy and histopathological examinations are also performed.

## 12.4 CONCLUSIONS

Nanomedicine has great potential to improve medical competences. Inconsistent classification, inadequate regulation, limited knowledge of its safety, and flaws in toxicity screening need to be addressed for this technology to provide the maximum benefit to mankind in general and in particular to cancer patients.

# An Overview of the Discovery and Development Process for Biologics

HEATHER H. SHIH, PAULA MILLER, and DOUGLAS C. HARNISH

## 1.1 INTRODUCTION

Biologics, also called biotherapeutics or biopharmaceuticals, are drug substances derived from living organisms or produced using biotechnology that are composed of biological entities such as proteins, peptides, nucleic acids, or cells [1]. They differ from small molecule (SM) drugs that are chemically synthesized and have low molecular weights. Some biologics, such as antibody–drug conjugates, consist of both a protein moiety and an SM component, both of which are required for the therapeutic action of the drug. Traditional biologics that have reached the market include vaccines and blood-derived factors. The advancement in modern biotechnology has brought forth new classes of biologics as exemplified by monoclonal antibodies (mAbs), Fc fusion proteins, recombinant proteins, and peptide drugs. Some early clinical success is now seen in several novel classes of biologics, which include antibody variants, novel protein scaffolds, RNA therapeutics, and cell-based therapies [2–5]. This chapter focuses on protein-based biologics, particularly mAbs because they represent the largest class of biologic drugs. By the end of 2011, the US Food and Drug Administration (FDA) had approved close to 40 mAbs and antibody variants as summarized in Table 1.1. Details on other forms of biologics such as vaccines and RNA drugs can be found in later chapters.

The first protein-based biologic drug, recombinant insulin Humulin, was approved in the United States in 1982 [6]. Since then the field of biologics grew steadily, with the biotechnology sector laying the foundation for both the drug discovery process and technology innovation. Around late 1990s, the pharmaceutical industry started to invest more in the development of biologics. This shift from a primary focus on SM drugs was largely due to patent expiration on these drugs and the concurrent fierce competition from generic SM drugs. In addition, the increasing difficulty to bring new drugs to the market because of tightened regulations and a lack of breakthroughs in the drug discovery process has also contributed to this shift.

**TABLE 1.1 List of Food and Drug Administration–Approved Antibody-Based Therapeutics Up to 2011 as Categorized by Types**

| Type of Ab-Based Therapeutics | Nonproprietary/ Trade Name | Ab Target or Fc Fusion Partner | Company |
|---|---|---|---|
| Human antibodies | Ipilimumab/Yervoy | CTLA4 | Bristol-Myers Squibb |
| | Belimumab/Benlysta | B-lymphocyte stimulator | Human Genome Sciences |
| | Ustekinumab/Stelara | p40 subunit of IL-12 and IL-23 | Johnson & Johnson |
| | Canakinumab/Ilaris | IL-1β | Novartis |
| | Denosumab/Prolia/Xgeva | RANKL | Amgen |
| | Ofatumumab/Arzerra | CD20 | Genmab |
| | Golimumab/Simponi | TNF | Centocor |
| | Panitumumab/Vectibix | EGFR | Amgen |
| | Adalimumab/Humira | TNF | Abbott |
| Humanized antibodies | Tocilizumab/Actemra | IL-6R | Roche |
| | Eculizumab/Soliris | C5 | Alexion |
| | Natalizumab/Tysabri | Alpha4 integrin | Biogen/Elan |
| | Bevacizumab/Avastin | VEGFa | Genentech |
| | Efalizumab/Raptiva | CD11a | Genentech |
| | Omalizumab/Xolair | Human IgE Fc | Genentech |
| | Alemtuzumab/ Campath-IH | CD52 | Genzyme |
| | Trastuzumab/Herceptin | Her2 | Genentech |
| | Palivizumab/Synagis | RSV protein F | MedImmune |
| | Daclizumab | CD25 | Roche |
| Chimeric antibodies | Cetuximab/Erbitux | EGFR | Imclone |
| | Infliximab/Remicade | TNFα | Centocor |
| | Basiliximab/Simulect | CD25 | Novartis |
| | Rituximab/Rituxan | CD20 | IDEC |
| Murine antibody | Muromonab-CD3/Orthoclone OKT3 | CD3 | Janssen-Cilag |
| Fab fragment | Abciximab/Reopro | CD43 | Centocor |
| | Ranibizumab/Lucentis | VEGFa | Genentech |
| | Certolizumab pegol/Cimzia | TNFα | UCB |
| Antibody conjugates | Brentuximab vedotin/Adcetris | CD30 | Seattle Genetics |
| | Tositumomab-I131/Bexxar | CD20 | GlaxoSmithKline |
| | Ibritumomab tiuxetan/Zevalin | CD20 | IDEC |
| | Gemtuzumab ozogamicin/Mylotarg | CD33 | Wyeth |

**TABLE 1.1** (*Continued*)

| Type of Ab-Based Therapeutics | Nonproprietary/ Trade Name | Ab Target or Fc Fusion Partner | Company |
|---|---|---|---|
| Fc fusions | Afilibercept/Eylea | VEGFR1 and 2 ECD | Regeneron, Bayer |
| | Belatacept/Nulojix | CTLA4 ECD | Bristol-Myers Squibb |
| | Romiplostim/Nplate | Peptide thrombopoietin mimetic | Amgen |
| | Rilonacept/Arcalyst | IL-1R ECD | Regeneron |
| | Abatacept/Orencia | CTLA4 ECD | Bristol-Myers Squibb |
| | Alefacept/Amevive | LFA-3 ECD | Biogen IDEC |
| | Etanercept/Enbrel | TNFRII ECD | Wyeth/Amgen |

Presently, the number of biologics on the market has reached more than 200, and the sales of biologics in 2009 reached $93 billion, with approximately one third of current pharmaceutical pipelines consisting of biologics [7]. Given that almost all of the large pharmaceutical companies have acquired infrastructures and committed resources to develop biologics, we will continue to see a robust growth in this sector in the coming years.

Compared with SM drugs, protein-based biologics have unique therapeutic features. A therapeutic protein usually exhibits exquisite specificity when binding to and modulating its molecular target, which often translates into low off-target toxicity and clinical safety. For example, therapeutic mAbs bind to their target molecules with affinities in the picomolar to low nanomolar range (e.g., [8]). Furthermore, the interaction occurs over a broad interface with multiple physical and chemical bonds formed between an antibody and its cognate antigen, resulting in an extraordinary binding specificity that allows the differentiation of binding partners that differ by as few as one amino acid or subtle conformational difference. On the contrary, the small size of an SM drug makes it prone to off-target binding to proteins other than its intended target, which may result in unacceptable levels of toxicities. A potentially short development cycle is another advantage for the development of biologics, particularly mAbs and recombinant proteins. A clinical candidate for mAb or recombinant protein can be generated and selected in as short as 3 to 5 years compared with typically 7 to 8 years for SMs.

Protein-based biologics have their own limitations. Presently, almost all protein-based drugs must be administered as intravenous or subcutaneous injections because oral delivery is not yet a viable route of administration. Furthermore, protein drugs do not readily penetrate cell membrane and blood–brain barrier (BBB) and therefore are limited to the modulation of peripherally located extracellular targets. The cost of goods to manufacture protein drugs is significantly higher than for SM drugs, which translates into a high drug price that exacerbates health management cost issues [9].

Based on these pros and cons associated with the development of biologics, presently the pharmaceutical industry strives to achieve a balanced portfolio consisting of both SM and biologic drugs. This chapter provides an overview of the discovery and development process for protein therapeutics with a primary focus on mAbs (Fig. 1.1). Additionally, the chapter summarizes the current status of the protein-based biologics field and discusses several future trends.

## 1.2 THE DISCOVERY PROCESS FOR MONOCLONAL ANTIBODIES

Monoclonal antibodies and mAb variants such as antibody–drug conjugates and Fc fusion proteins are a major class of biologics. This section describes in detail the discovery process for mAbs. Later chapters illustrate the process for several other forms of biologics such as vaccines and RNA therapeutics.

In mammals, antibodies are proteins found in the blood that are produced by B cells from the humoral immune system in defense of foreign organisms recognized by the host system. Also known as immunoglobulins, antibodies can be categorized into five classes or isotypes, namely IgM, IgD, IgG, IgE, and IgA (reviewed by Schroeder and Cavacini [10]). IgG is the predominant class in therapeutic antibodies. An IgG molecule consists of two heavy chains and two light chain interlinked by disulfide bonds (Fig. 1.2). Each chain has an N-terminal variable region (Fv) and a C-terminal constant region. The variable region of each pair of heavy and light chains has six hypervariable loops (three per chain) called

**FIGURE 1.1** Major phases and general timelines of the drug development process for biologics. BLA: biologics license application; GLP: good laboratory practice; GMP: good manufacturing practices; IND: investigational new drug; NDA: new drug application.

*complementarity determining regions* (CDRs) that form the antigen binding region at the tip of the IgG molecule. The heavy and light chains in an Fv fragment can be joined via a linker using recombinant DNA technology and produced as a single-chain Fv (scFv) molecule, which is used in phage display technology as a method to generate therapeutic antibody candidates (see later discussion). Papain digestion of an IgG yields three components: two Fab fragments and an Fc fragment. A Fab molecule can be generated via molecular engineering into a therapeutic agent. Currently, three Fab-based antibody drugs are on the market: abciximab, ranibizumab, and certolizumab pegol (Table 1.1). The Fc fragment exhibits effector functions, namely the ability to engage immune system to kill antibody opsonized molecules. In addition, the binding of Fc to bacterial protein A and protein G has been applied to the purification of therapeutic antibodies at industrial manufacturing scales. Furthermore, Fc binds to the neonatal Fc receptor (FcRn) expressed on endothelial cells. Upon uptake by endothelial cells, FcRn recycles IgG molecules back into circulation, thus conferring a long *in vivo* half-time to IgG [11]. Via molecular engineering, the Fc fragment can be fused to another protein fragment such as a soluble factor or the extracellular domain of a cell surface receptor. The resulting Fc fusion proteins represent one type of antibody-based therapeutics (Table 1.1 and Fig. 1.2).

The advancement in molecular and cellular biology has transformed the isolation, molecular engineering, and production of recombinant mAbs into an industrial drug-making process. Compared with other protein drugs, mAbs demonstrate superior properties as therapeutic molecules. They typically exhibit exquisite specificity to their molecular targets and minimal off-targeting binding. The bivalency of each antibody molecule contributes to its extraordinarily high binding strength (avidity) as the summation of the affinity from each half of the molecule. It also confers a cross-linking function that can be applied to its therapeutic function. The effector functions associated with the Fc domain allow the molecule to effectively mobilize the immune system to attack and kill tumor cells when used to treat cancers. mAbs are highly stable proteins with natural resistance to biological and chemical degradation. They tend to be amenable to expression and purification at manufacturing scales. They typically exhibit long *in vivo* half-lives, which allow infrequent administration in patients. As a result of these multifaceted advantages associated with mAbs, the pharmaceutical industry has focused on the development of mAbs as a major class of biologic drugs.

In many pharmaceutical and biotechnology companies, the development process for therapeutic mAbs is well established and analogous to that for SM drugs. It can be generalized into four stages: target selection, screening preparation, lead selection and optimization, and clinical candidate selection. The discovery phase is followed by a preclinical development process and ultimately the clinical testing of the selected mAb candidate in human subjects. This section describes relevant research activities that take place in each of the four discovery stages leading to the selection of a clinical candidate protein. The major differences in the respective processes for developing biologics and SMs are discussed at the end of this section.

**FIGURE 1.2** Major types and properties of therapeutic antibodies and antibody variants. (a) Depiction of a whole immunoglobulin molecule. The major domains and their associated functions are indicated. *Light lines* represent disulfide bonds. Fab: antigen binding fragment; Fc: crystallizable fragment; Fv: variable fragment. (b) Major forms of therapeutic antibodies. CDR: complementarity determining region. (c) Major forms of antibody variants. All but one (single-chain variable fragment [scFv]) drug is currently approved. The scFv is used in drug discovery to identify drug candidates.

### 1.2.1 Target Selection

A target is a biological entity in patients that can be specifically and effectively modulated by a drug to ameliorate or cure a pathological condition. Selecting a drug target is usually the first step in a drug development program, although there are exceptions to the rule when drug candidate screening is carried out using a functional readout without predefined targets. In a majority of such cases, the target is identified retrospectively after the functional candidates have been selected.

A novel target is often identified either during the studies of biological pathways underlying a disease or as a result of disease target identification efforts frequently using genomic technologies such as transcriptional profiling, proteomics, and genome-wide gene association studies. Usually a target must be "validated" before the initiation of a drug discovery program. *Target validation* refers to a process of collecting clinical and experimental data to predict a beneficial therapeutic outcome from a hypothesized modulation of a selected target. A typical target validation data package often includes some or all of the following elements: (1) the target is

aberrantly expressed in the disease tissue(s) (the polymorphism of the target gene in humans has a strong association with the disease); (2) in cellular and animal models, overexpression or deficiency of the target leads to a biological outcome consistent with the expected therapeutic outcome; and (3) pharmacologic modulation of the target gives rise to expected results in cellular and animal models. A drug discovery project may begin with some evidence that the target is tied to the pathogenesis of a disease, in which case target validation becomes a continuous endeavor carried out in parallel to the generation of therapeutic candidates.

### 1.2.2 Screening Preparation

With enough confidence that therapeutic modulation of a selected target can treat a pathological condition, screening preparation can be initiated. The goal of this drug discovery stage is to generate all the reagents, functional assays, and cellular and animal models to carry out a variety of functional screens in order to select the best therapeutic candidate for human testing. This process starts with a well-thought-out screening plan that defines the primary, secondary, and tertiary screening methods encompassing *in vitro* and cellular assays and animal studies. The plan should end with the selection of a clinical candidate. Included in the plan are estimated timelines for each step, "go" and "no-go" decision points, foreseeable challenges, and mitigation plans.

Screening reagents and assays are the "bricks and mortar" to a successful selection of a therapeutic candidate. The reagents include all the essential materials needed to develop and carry out the screening assays such as cDNA and expression vector for the target, purified target protein, and cells that express the target for testing candidate antibody functions. The screening assays allow the selection of mAb candidates based on target binding and biological activities.

For drug discovery projects, animal models are used to determine the efficacy, pharmacokinetics (PK), pharmacodynamics (PD), and safety of a drug candidate. The development of relevant animal models often takes months to years and should be initiated early in the drug discovery process.

### 1.2.3 Lead Selection and Optimization

Lead selection is a process in which a rigorous screening scheme is applied in order to identify a candidate that meets the defined drug-like criteria of functional and molecular properties. The leads from this process are early drug candidates and may not have all the drug-like properties such as minimal immunogenicity profile, favorable biochemical and biophysical properties, and optimal PK properties. These properties can be subsequently optimized using a variety of technologies and ultimately developed into a viable clinical candidate.

Three major technologies have been used to develop the mAb drugs currently on the market: hybridoma, phage display, and human transgenic mouse technologies.

The hybridoma technology is a classic mAb generation technology first developed by Kohler and Milstein in 1975 [12]. Using this method, rodents are immunized

with target proteins to induce a high-titer response indicative of the generation of high-affinity rodent antibodies. The splenocytes are subsequently harvested from responding animals and fused with myeloma cells to create clonal hybridoma cells capable of secreting antibody molecules. Each hybridoma clone generates a single IgG, which is the basis for the name of mAbs. The hybridoma clones can be perpetually expanded in cell culture to provide nondepletable sources of therapeutic candidate molecules. For clinical manufacturing, however, hybridoma culture is not well suited for an industry process because of the inefficiency of these cells producing high concentrations of antibodies. Instead, DNA sequences of the IgGs from hybridoma clones are determined, and recombinant mAbs are generated in industrial quantities for clinical testing. The ultimate therapeutic recombinant mAbs have often been modified from the original rodent hybridoma mAbs using antibody engineering methods such as humanization (see later discussion).

As demonstrated by its long history, hybridoma technology is a reliable method to generate high-affinity antibodies to many protein targets and is still widely used in industry to derive early mAb therapeutic candidates. The shortcomings of this method include a relatively long cycle time from immunization to the identification of desirable mAbs (3–4 months) and difficulties to generate antibodies to proteins that are toxic to or immunotolerated by the host animal.

In contrast to the utilization of an *in vivo* system central to the hybridoma technology, phage display is a purely *in vitro* system. As first demonstrated by McCafferty et al. [13], a scFv or the Fab fragment of an IgG can be displayed on the surface of a phage particle as a fusion protein to the gene 3 phage coat protein. Built upon modern recombinant DNA technology, phage display is an elegant technology to derive antibody fragments that bind to a protein of interest. A library constituting a vast number of diverse scFv or Fab sequences up to the order of $10^{11}$ is generated. The diversity of the scFv or Fab sequences is derived from either a natural human antibody repertoire isolated from immune tissues or a synthetic repertoire where recombinant DNA technology is used to generate sequence variations [14]. During the screening process, the phage-displayed scFv or Fab is allowed to bind to the target protein and is separated from the nonbinders. The sequence of the binding scFvs or Fabs can be determined from the bacterial clones producing these "functional" phage particles. The selected scFv candidates are genetically converted back to full IgG molecules that are functionally indistinguishable from natural IgGs.

Compared with the hybridoma technology, phage display technology offers a quick way to find functional antibody fragments in a matter of weeks. In addition, the *in vitro* experimental conditions are highly amenable to manipulations and can facilitate the isolation of antibodies to difficult targets that may not be easily generated via a hybridoma approach. However, phage display has been a proprietary technology and thus is less accessible to general use than hybridoma technology. This may change given that the patent on gene 3 fusion technology has expired in 2012. To date, the majority of approved mAbs have been derived from hybridoma technology with adalimumab and recently belimumab being the only phage-derived mAb on the market. It is believed that this technology is reaching its maturity and will give rise to many more approved mAb drugs in the coming years [15].

The human transgenic mouse technology is built upon the hybridoma technology to directly generate fully human mAbs in immunized transgenic mice that express human IgGs in place of murine IgGs. The best known human transgenic mouse technologies are Medarex's HuMab-Mouse and Abgenix's XenoMouse. New strains of human transgenic mice will continue to be generated. Five therapeutic mAbs derived from this technology have gained FDA approval (Table 1.1). Despite the success of using this technology to bring forth marketed therapeutic mAbs, its proprietary nature limits general access and wide usage.

After a mAb lead is identified, it often needs to be optimized before being selected as a therapeutic candidate. Humanization has become widely used to maximize the content of the human sequence in a mAb of rodent origin to greater than 95% (reviewed by Almagro and Fransson [16]). Compared with the parental rodent mAb, the "humanized" mAb has significantly reduced "foreignness" and thus an improved safety profile in relation to the immunogenicity of the molecule (see later discussion). The process in general takes 3 to 6 months with a near 100% success rate to yield a humanized molecule with activity comparable to the parental rodent mAb.

Affinity maturation is another widely used antibody optimization method used to significantly increase the antigen binding affinity of the parental antibody [17]. Either selected CDR sequences or the entire variable domains of the parent antibody are randomized to create a library of mutant antibody molecules, from which those with improved antigen binding affinity are selected. Two widely used enabling technologies for affinity maturation are phage display and ribosomal display. An increase in binding affinity in the range of 10- to 100-fold can be achieved from this optimization process.

Fc engineering is a technology aimed at endowing optimal effector functions and half-life extension to the parental mAb. The effector function of a mAb often plays a role in its therapeutic function such as the killing of cancer cells via antibody-dependent cellular cytotoxicity (ADCC) or antibody-mediated complement-dependent cytotoxicity (CDC). In other cases such as targeting receptors on normal cells, it is beneficial to reduce or abrogate the effector function of a mAb to avoid deleterious effects resulting from potential ADCC or CDC. Mutations in the Fc that up-or down-regulate the effector functions of an IgG have been vigorously studied and presently applied to candidate molecules in clinical testing [18]. Additionally, Fc mutations that increase IgG interaction with FcRn, a receptor on endothelial cells that helps recycle a bound IgG back into circulation, have been shown to significantly improve the serum half-life of an IgG [19].

### 1.2.4 Selection of a Clinical Candidate

The selection of a clinical candidate is a process in which a lead mAb has been thoroughly evaluated for its biological activities and molecular characteristics. The biological activities refer to desirable biological functions as characterized in a combination of *in vitro* systems, cellular systems, and animal models. Based on these characterizations, a clinical candidate molecule is deemed to have met predefined efficacy and safety criteria for clinical testing in human subjects. The molecular

characteristics refer to the intrinsic behavior of a candidate molecule that must be amenable for manufacturing as well as delivering into human patients. The molecule must demonstrate acceptable levels of expression in a manufacturing production system, display favorable physiochemical characteristics, and exhibit desirable solubility in a formulation used for clinical administration. Other considerations for clinical candidate selection that need to be taken into account include commercial assessment, competitive landscape, and intellectual properties. After a molecule is selected as a clinical candidate, it triggers a number of preclinical development activities, leading to investigational new drug (IND) filing and the commencement of clinical studies. It is not unusual that a candidate selected from early stages of discovery process fails candidate selection because of various reasons associated with the criteria described.

### 1.2.5 Key Differences in the Discovery Process for Monoclonal Antibodies Versus Small Molecule Drugs

Although the general concept and overall drug discovery process from selecting a target to nominating a clinical candidate are similar for mAbs and SMs, there are some key differences. In general, the discovery cycle time for mAb drugs can be significantly shorter than that for SMs. Therapeutic mAb discovery is becoming a platform process that allows rapid identification, characterization, and production of lead candidates. Whereas it is very challenging to optimize an initial SM "hit" to turn it into a drug candidate amenable for human testing, many drug-like properties of mAbs are intrinsic to this class of molecule. This section discusses several specific areas that illustrate key differences in this process for the two different classes of drugs.

***1.2.5.1 Therapeutic Targets*** Protein therapeutics including mAbs are best suited for modulating molecular targets expressed on the surface and outside of the cells. Proteins lack intrinsic abilities to penetrate cell membranes to reach intracellular targets. SMs can access targets localized either inside or outside of a cell. In addition to the cellular location of a target, physiological barriers such as the BBB in the central nervous system (CNS) can greatly limit the passage of large molecules such as mAbs from the circulation into the brain.

The mode of target modulation can be different for mAb and SM drugs. Being structurally small, an SM drug typically modulates a target by docking onto a small pocket in a protein such as an adenosine triphosphate (ATP) binding site of a kinase and functionally altering the target molecule. It is difficult for SM drugs to disrupt protein–protein interactions that take place over large binding interfaces, a task that can be easily achieved by mAbs.

***1.2.5.2 Screening Scale*** The screening scales are significantly different for the two classes of drugs during the lead discovery phase. Whereas screening tens to hundreds of thousands of chemical compounds is a routine practice for a SM project, the screening scale is much smaller for mAbs, which is typically in the range

of thousands of test molecules. For mAbs, a build-in enrichment process before the screening step facilitates a reduction in the screening scale. For hybridoma antibody generation, the immunized rodents are an *in vivo* selection system that filters out nonspecific antibodies from the naïve antibody repertoire and enriches for high-affinity and antigen-specific antibodies. For phage antibody generation, the initial *in vitro* selection process enriches populations of phage particles that display target-binding antibody fragments. In both processes, the screening is carried out primarily to deconvolute single clone binding activities from an enriched binder pool. SM lead generation lacks this selection and enrichment process and generally relies on large-scale screening to derive candidate molecules.

***1.2.5.3 Need for Surrogate Molecule*** Surrogate antibodies are pertinent to many mAb drug discovery projects. Because of its exquisite specificity, a mAb developed to target a human protein in many cases fails to bind to its orthologous proteins in other animal species. The evaluation of a drug candidate in animals for efficacy, safety, and PK and PD, however, is important, and these are required preclinical studies. Therefore, in many cases, in parallel to the generation of the therapeutic candidate, a surrogate antibody is also created that is functionally equivalent to the therapeutic candidate and binds the target ortholog expressed in the appropriate animal species used for drug discovery models, most often mouse. It is noteworthy that SMs are not entirely excluded from the issue of lacking species cross-reactivity. However, the surrogate approach is not a routine practice during the discovery process of an SM drug.

***1.2.5.4 Drug Properties*** Lipinski's rule of five is a general set of rules to evaluate drug-like molecular properties of a SM compound [20]. Similarly, there are emerging rules to describe the drug-like physicochemical properties for protein drug candidates. Given their distinctive molecular compositions, SMs and mAbs each have uniquely defined drug-like properties. For SMs, these properties are associated with the presence of H-bond donors and acceptors, molecular weight, and partition coefficient; for mAbs, they are based on expression levels, aggregation propensity, stability, solubility, and posttranslational modifications.

The two classes of drugs also bear different intrinsic toxicity risks. A SM is prone to bind to unintended molecular targets in humans and elicit off-target toxicity, which may not be manifested in an *in vitro* screen or animal toxicity models. On the contrary, mAbs in general exhibit low off-target toxicity because of highly specific binding to their molecular targets.

Immunogenicity is a unique safety concern for protein therapeutics, including mAbs. The immune system of a patient who receives a protein drug can recognize it as a foreign entity and react with an antidrug response. The consequence of such immunogenicity response ranges from negligible or mild effects to severe anaphylactic response [21]. Presently, there are few methods at the preclinical stages to accurately predict the immunogenicity of a clinical protein drug candidate, albeit that a number of practices are used to reduce the likelihood of immunogenicity, which include the prediction and elimination of T-cell epitopes in the mAb molecule and the

utilization of *ex vivo* assays to monitor the potential of a mAb to activate T cells [22]. A vigorous determination of antidrug antibody response is mandated to monitor the immunogenicity of a protein drug during clinical development.

## 1.3 MANUFACTURING PROCESS DEVELOPMENT FOR BIOLOGICS

### 1.3.1 Introduction

After a candidate with appropriate efficacy and safety has been identified, the research focus shifts to process development and manufacture of clinical trial materials. A robust manufacturing process is critical to ensure that appropriate quality is reproducibly achieved in the packaged clinical supplies. Compared with SMs, biotherapeutics are large, complex molecules that fold to incorporate specific tertiary structure and are subject to a variety of posttranslational modifications. As such, a biotherapeutic drug is a complex mixture of species. Furthermore, the specific composition of the mixture is profoundly affected by the manufacturing process as well as handling and storage conditions. Therefore, to reproducibly control the specific composition of the mixture and the quality of the resulting clinical supplies, it is necessary to understand the critical processing parameters during manufacture and handling and storage conditions and how they ultimately impact product quality.

### 1.3.2 Early Assessment of Discovery Candidate(s)

During the transition from the discovery research phase to the clinical development phase, a candidate or several candidates are typically assessed for suitability for manufacturing process development. mAbs are a special class of biologics that share common structural features that make them well suited to platform production and purification. Platform production involves defining a set of conditions for production that are suitable for most antibodies, albeit the platform may not be optimal for any given candidate. Antibodies are typically assessed for fit in a defined platform for process development and production. This usually involves an assessment of expression in mammalian cell lines or titer based on data available from the discovery process, which may include data from transient expression or pools derived from stable transfection into a Chinese hamster ovary (CHO) host cell line, for example. In transient HEK-293 systems, titers (i.e., expression levels) of less than 50 mg/l may present a potential concern and would likely require close monitoring during development to ensure acceptable expression titers are achieved in mammalian cell lines resulting from stable transfection.

Evaluation of a candidate's propensity to aggregate and to undergo degradation in a preferred formulation or set of formulations is an important part of the early assessment process. Aggregation can occur during all phases of production, and controlling the levels of aggregate in the final product can be challenging. In addition to aggregation, significant degradation pathways such as oxidation,

deamidation, isomerization, and peptide bond cleavage are also evaluated early, typically at multiple temperatures. Often accelerated stability studies are carried out under more extreme conditions to understand the major degradation pathways for a specific candidate or set of candidates. It is important to recognize that because different degradation pathways may be accelerated at different rates, these studies need to be analyzed carefully and may not represent the distribution or even the specific composition of the various impurities under standard conditions [23,24].

The early assessment of candidates is largely intended to identify those that may present significant challenges during development. If multiple candidates are being considered for development, the selection can be based on a panel of data including, but not limited to, efficacy, tolerability, and stability. Early formulation studies can help to inform the selection decision. If a candidate shows particularly poor stability during the early assessment, it can be a significant or determining factor in candidate selection. It is also important to understand that although an early assessment can highlight potential challenges for a specific candidate, it does not replace subsequent development work; rather, it is the foundation for the preclinical development that follows.

### 1.3.3 Bioprocess Development and Manufacture

After a development candidate has been identified, cell line development begins with transfection of a suitable expression vector into a host cell line. Mammalian expression systems predominate for the large-scale production of antibodies because they can perform complex posttranslational modifications that are important for correct protein folding, stability, multimer formation, and secretion into the medium [25]. CHO cell lines are some of the more commonly used host cell lines for antibody production and use selectable markers based on dihydroxy folate reductase (dhfr) and glutamine synthetase (GS) that are available in suitable stable expression vectors for these cell lines [26,27]. Cell line stability is another key consideration during development. Typically, a good production cell line will be stable for 70 to 100 generations. The primary goal is to create a stable cell line with the appropriate growth properties and a high specific productivity ($Q_p$). The selection process is carried out over progressively increasing scales from microtiter plates to small bioreactors. During the selection process, the material that is produced is used to develop or confirm a suitable formulation and downstream processing methods and to evaluate analytical platform methods. The availability of this material and material produced during subsequent cell culture process development for parallel analytical and pharmaceutics development is critical for an efficient and integrated strategy for production of clinical trial material. After a clone is selected, a master cell bank (MCB) is prepared. The MCB, or a working cell bank (WCB) prepared from the MCB, is used in the scale-up and production of material for enabling regulatory toxicology studies and clinical trials. It is worth noting that the MCB is prepared under good manufacturing practices (GMP) conditions and is used to generate all the antibody supplies for the lifetime of the product if the candidate is successful. Thus, the preparation of an MCB represents the earliest component of the commercial process.

For mAbs, platform cell culture process development presents a number of challenges, including the need to adequately control for protein misfolding, aggregation, oxidation, deamidation, proteolysis, and glycosylation variants. Each of these product-related impurities should be monitored and controlled under the platform conditions. In some cases, the platform process may need to be modified to address candidate specific issues.

Scaling the process involves thawing vials from an MCB or WCB. This initial inoculum is expanded in shake flasks and small bioreactors and is then transferred to progressively larger seed reactors before transfer of the cell mass to the production bioreactor. There are two growth phases during fermentation. During the initial growth phase, the primary objective is to increase the viable cell mass; during the protein production phase, cell growth slows, and antibody expression and secretion ensue. A typical mAb cycle time in the production bioreactor is 10 to 12 days.

The common structural features of antibodies make them well suited to platform purification. Most, if not all, large-scale purification schemes incorporate protein A or MabSelect chromatography as the first downstream purification step. The protein A–immobilized ligand binds to the Fc region of antibodies while host cell proteins (HCPs), DNA, and other process-related impurities flow through in the mobile phase. Typically, protein A chromatography affords product in greater than 90% purity after elution from the column at low pH [28]. Ion exchange chromatography is commonly used to further purify the antibody product from HCPs, DNA, and other process- and product-related impurities. Additional filters or chromatography steps can be used to address candidate-specific issues.

Because antibodies are produced in mammalian cell culture, which can harbor viruses harmful to humans, two orthogonal methods to remove viral particles are typically incorporated in the downstream process in addition to the chromatography steps. These generally include a low pH viral inactivation step followed by viral filtration.

For first in human (FIH) clinical trials, it is generally acceptable to demonstrate clearance of two representative viruses, assayed once using new resin; however, because subsequent trials in Europe would fall under the 2008 European Medicines Agency (EMA) guidelines and because viral clearance studies are expensive and time consuming, more and more companies are choosing to comply with the more recent EMA guidelines in US trials even at early stages of development. Viral clearance validation for phase 3 and biologic license application (BLA) filing is much more comprehensive, including, but not limited to, demonstrating clearance for a minimum panel of four representative viruses, assayed in duplicate using new and recycled resins [29].

The last downstream step is commonly ultrafiltration/diafiltration (UF/DF) to reduce the volume, increase the protein concentration to an appropriate level for formulation, and incorporate selected stabilizing excipients to facilitate storage and preparation of the fully formulated drug product. Production of clinical-grade material involves execution of multistep processes, and often multiple facilities are required to support manufacture of the drug substance, the drug product, and the required analytical testing. To simplify logistics, it is often desirable to develop and

define hold conditions for downstream process intermediates and storage conditions for the drug substance. The downstream process for production of drug substance is designed to eliminate or reduce impurities and degradation products within acceptable limits and to minimize formation during processing to afford a drug substance with the appropriate quality.

### 1.3.4 Formulation Process Development and Manufacture

All proteins are subject to various degradation pathways. Degradation can occur during the process to prepare the drug substance or drug product and during their storage in the liquid, frozen, or solid state. An understanding of the various degradation pathways is critical not only to minimize and remove impurities during production but also to maintain the appropriate quality attributes of the final drug product during and after production and during shipping and storage.

Degradation of proteins can be generally categorized as either physical or chemical. Physical degradation includes surface adsorption, denaturation, and aggregation. Examples of chemical degradation include deamidation, oxidation, isomerization, fragmentation, and cross-linking.

As the demand for subcutaneous and intramuscular injection routes of administration to support patient focused delivery approaches increases, the ability to formulate proteins at increasingly higher concentrations has become a major focus in the pharmaceutical industry. These high concentrations present unique challenges, including the possibility for aggregation, precipitation, and high-viscosity solutions that can be difficult to administer to patients.

Although antibodies share a common framework, many of their degradation pathways are associated with specific primary sequences or the unique antigen-binding regions (i.e., CDRs). Additionally, the rates of various degradation pathways for a single antibody differ under a specific set of conditions, including pH, temperature, and concentration, as well as processing and handling conditions. Therefore, determining the optimal formulation and storage conditions can be very candidate specific. Most platform strategies strive to define a formulation or set of formulations that are suitable for the majority of candidates but not optimized for any specific candidate. This approach has been quite successful for antibodies but does not eliminate the need to understand the degradation pathways for a specific candidate and document that the selected formulation(s) are suitable for that antibody. This is particularly important for antibody drug candidates that ultimately become successful commercial products because the dose and dosage form generally evolve as development progresses from FIH studies to regulatory approval and launch.

### 1.3.5 Analytical Method Development and Manufacture

In the previous sections, a common theme is the importance of understanding how the production process, formulation, handling, and storage conditions affect the critical quality attributes of biological drug candidates. Key to this understanding is the ability to monitor and measure the process- and product-related impurities

observed during development and production and relate them to the efficacy and stability of a given candidate. A variety of methods can be used to identify, monitor, and quantify the various process- and product-related impurities.

Of the various process-related impurities, HCPs, DNA, and endotoxins are of primary concern because they can have negative side effects on patients. Endotoxins, or pyrogenic lipopolysaccharides (LPS), are derived from Gram-negative bacteria such as *Escherichia coli*. In mammalian production hosts, endotoxins can be introduced into a process via raw materials [30,31]. DNA can be extracted and quantified by standard techniques, including quantitative polymerase chain reaction (qPCR). Additionally, a number of host cell–specific enzyme-linked immunosorbent assay– (ELISA-) based assays to quantify HCP and DNA are also available [32].

Product-related impurities are equally important to monitor, and a variety of analytical methods have been used to quantify the physical and chemical degradation pathways of proteins. Aggregation is one of the more significant types of physical degradation. A variety of methods for detection and quantification can be used, depending on the size and type of aggregates. Size exclusion chromatography–high-performance liquid chromatography (SEC-HPLC) supplemented with appropriate orthogonal methods is a commonly used analytical strategy. Analytical methods to sufficiently characterize glycosylation patterns are extremely important for antibodies. Although heterogeneity in glycosylation patterns is not unusual, proper glycosylation and distribution of variants may be critical for proper antibody function [24]. Oxidation, deamidation, and fragmentation are some of the more common chemical degradation pathways observed for antibodies. Fragmentation can be detected using methods that separate intact and fragmented molecules based on size. Deamidation is the primary source of charge heterogeneity, and initial identification may involve detection of differences in charge distribution by isoelectric focusing (IEF) or high-performance cation exchange chromatography [33]. Similar methods can be used to assess oxidative degradation.

The methods described can be used for most protein therapeutics, and many are amenable to platform development for antibodies. Platform analytical methods are designed to detect and quantify the expected degradation pathways for antibodies, although the impurity profile for any specific antibody tends to be unique. Ultimately, however, for each candidate, it is necessary to develop candidate-specific identity and bioassays. Often simple binding ELISA-based (or BIACore) bioassays are initially developed for early clinical development. It is necessary, however, to develop a cell-based or functional bioassay for later stage clinical trials.

### 1.3.6 Project Management and Critical Path to the Clinic

Production of clinical supplies requires close collaboration among multiple scientific lines. Often multiple teams, each with a different focus, are working in an integrated and iterative way during research, process development, and manufacture with multiple hand-offs between these teams. More often than not, research, process development, and manufacture occur over multiple locations and long periods of time, during which personnel move in and out of various roles on the teams.

Furthermore, outsourcing some or all of the process development or manufacturing to contract manufacturing organizations (CMOs) is becoming increasingly common, which brings with it additional complexity. The outsourced work typically requires a technology transfer and some level of oversight personnel to facilitate and act as technical consultants. The lead times to identify a CMO, conduct a quality audit, negotiate a contract, and schedule a slot for the work can cause delays if appropriate planning is not in place. Moreover, managing the contract and the payment schedule can require additional nontechnical oversight. Although the pharmaceutical industry's focus on speed to the clinic in recent years has fueled the implementation of platform process development for antibodies, the technical and business complexities have necessitated careful planning and project management to facilitate and streamline platform antibody production across scientific lines and to ensure there is an appropriate balance between speed, cost, and quality.

In an accelerated development strategy, the availability of representative protein generally defines the critical path to the clinic: first the material from cell culture development to enable the parallel development of the downstream purification process, analytical methods, and a suitable formulation; then the good laboratory practice (GLP) material for a regulatory toxicology study; and finally, packaged GMP supplies with supporting stability studies to enable clinical dosing. Because GMP supplies can be prepared while the regulatory toxicology is underway, from a production perspective, it is the process development and manufacture of GLP material for regulatory toxicology that is on the critical path to the clinic.

## 1.4 REGULATORY REVIEW AND APPROVAL FOR BIOLOGICS

### 1.4.1 US Drug Law

The basis of US drug law is the Federal Food, Drug, and Cosmetic Act (FD&C Act) of 1938. Its passage by the US Congress required new drugs (prescription and over-the-counter drugs, medical devices, foods, and cosmetics) to be shown safe and effective before marketing and ushered in the modern area of drug development. In 1944, the Public Health Service Act (PHS Act) was subsequently passed to provide the pathway to regulate the licensure of biologic products such as vaccines, blood products, allergenic products, and other products such as mAbs. The significance of this is that for marketing of a new product, a New Drug Application (NDA) is used for SM drugs subject to the drug approval provisions of the FD&C Act, and a biologics license application (BLA) is required for biological products subject to licensure under the PHS Act. The Prescription Drug User Fee Act (PDUFA) required drug and biologics manufacturers to pay fees for product applications and supplements, and other services.

***1.4.1.1 Food and Drug Administration Modernization Act of 1997*** The Food and Drug Administration Modernization Act (FDAMA) reauthorized PDUFA and, at the time, mandated the most wide-ranging reforms in FDA practices since 1938.

Provisions include measures to regulate advertising of unapproved uses of approved drugs, to increase patient access to experimental drugs, and to accelerate review of important new medications. In addition, the law provided for an expanded database on clinical trials accessible by patients.

***1.4.1.2 Best Pharmaceuticals for Children Act of 2002*** The Best Pharmaceuticals for Children Act (BPCA) continued the exclusivity provisions for pediatric drugs as mandated under the FDAMA, in which market exclusivity of a drug is extended by 6 months, and in exchange, the manufacturer carries out studies of the effects of drugs when taken by children.

***1.4.1.3 Pediatric Research Equity Act of 2003*** The FDA is given clear authority under the Pediatric Research Equity Act (PREA) to require sponsors to conduct clinical research into pediatric applications for new drugs and biological products.

***1.4.1.4 Food and Drug Administration Amendments Act (FDAAA) of 2007*** Among other things, the FDAAA reauthorized PDUFA, PREA, and the BPCA. Other major topics covered within this wide-ranging legislation are new FDA authorities for requiring label changes and postmarketing studies, new and expanded requirements for registration of clinical trials and disclosure of results, formation of the Reagan-Udall Institute in support of the FDA's Critical Path initiative, new conflict of interest rules for the FDA Advisory Committee members, and new rules on citizen petitions.

Another landmark act was the Federal Register Act of 1935, which established the basic legal structure of the US regulatory system. The Administrative Procedure Act of 1946 added procedural requirements to ensure due process and public participation. As a result of the Federal Register Act, the daily *Federal Register* provides a single, uniform publication for executive agency rules, notices, and presidential documents, thus providing an official notice of a document's existence, its contents, and its legal effect. From this came the Code of Federal Regulations (CFR). It is a codification of rules published in the *Federal Register* by the executive departments and agencies of the federal government.

### 1.4.2 Food and Drug Administration Overview

The FDA is a consumer protection agency and falls within the executive branch of the US government under the Department of Health and Human Services (DHHS). The FDA has a broad range of responsibilities, including regulation of drugs, biologics, medical devices, animal drugs, food, and cosmetics. The FDA's major activities are: (1) reviewing new products; (2) ensuring safe drug manufacturing and handling; (3) monitoring for new risks, standards, and regulations (4) research; and (5) enforcing actions to protect public health. There are five FDA centers with the Center for Drug Evaluation and Research (CDER) and Center for Biologics Evaluation and Research (CBER) responsible for providing regulatory guidance for new drug products while ensuring that marketed products are safe and effective.

The CBER reviews products according to type (e.g., vaccines), and the CDER reviews products by area of medicine (e.g., oncology). The CDER does review certain biologic agents, proteins intended for therapeutic use that are extracted from animals or microorganisms. These include most of the recombinant proteins such as mAbs, cytokines, and growth factors as well as the more traditional pharmaceuticals. The other biologic products, including blood and blood components, cellular and gene therapy products, vaccines, antitoxins, allergenic extracts, and venoms, are reviewed by the CBER.

### 1.4.3 Drug Development in the United States

The major phases of the drug development process in the United States are discovery or preclinical testing, phase 1 FIH studies (typically a single ascending dose and multiple ascending dose study), a phase 2 proof of mechanism study, and phase 3 pivotal registration studies in the intended patient population followed by market approval with potential phase IV postmarketing commitments. In the United States, it takes anywhere from 10 to 15 years for an experimental drug to move from the laboratory to the patient. Approximately only one in 5000 synthetic SM pharmaceuticals proceed from discovery to approval.

To get approval in the United States to begin clinical testing, the sponsor must submit an IND application to the FDA. The contents of the IND provide the data and rationale to support proceeding with human clinical testing of the drug. The IND application must contain information in three broad areas. The first is animal pharmacology and toxicology studies that permit an assessment as to whether the product is reasonably safe for initial testing in humans. The second is manufacturing information pertaining to the composition, manufacture, stability, and controls used for manufacturing the drug substance and the drug product. This information is assessed to ensure that the company can adequately produce and supply consistent batches of the drug. Finally, the clinical development plan is required with detailed protocols for the proposed clinical studies to allow an assessment of whether the initial-phase trials will expose subjects to unnecessary risks. Also, information should be provided on the qualifications of clinical investigators as well as commitments to obtain informed consent from the research subjects, to obtain review of the study by an institutional review board (IRB) and to adhere to the IND regulations.

In general, an NDA or BLA is filed at the completion of all three clinical trial phases (with the exception of accelerated approval). It contains all of the scientific information (studies in animals and humans) and addresses the safety and efficacy of the drug. The goals of a NDA or BLA are to provide sufficient information to permit the FDA reviewer to reach the following key decisions: (1) that the drug is safe and effective in its proposed use(s); (2) the benefits of the drug outweigh the risks; (3) the proposed labeling (package insert) is appropriate for what it should contain; and (4) methods used in manufacturing the drug and the controls used to maintain the drug's quality are adequate to preserve the drug's identity, strength, quality, and purity.

After the FDA receives a NDA or BLA, the review period is defined by the PDUFA, and the FDA has 60 days to accept or refuse to file. The FDA begins the review by assembling a review team. Based on requirements or to gain expert input, the FDA may also seek the advice of an advisory committee. Its role is to provide independent advice that contributes to the quality of the agency's regulatory decision making and lends credibility to the product review process. The ultimate decision to approve is based on whether the drug's benefits outweigh the potential risks. After a recommendation (e.g., approved or complete response) on the application is reached by the reviewers and their supervisors, the director of the applicable Drug Review Division or office evaluates the decision. After the product is approved, the product can be legally marketed in the United States starting on the date of approval.

### 1.4.4 US Generic and Biosimilar Legislation

After a product is marketed, it has a finite time of exclusivity before a generic competitor can enter the marketplace. This time frame is dictated by the type and quality of approved patents associated with the innovator product. This patent protection provides the innovator drug maker time to recoup its development costs associated with bringing the therapy to market and thus also provides incentive for continual new drug development. The current system of generic drug approval was established by the Drug Price Competition and Patent Term Restoration Act of 1984 (also known as the Hatch-Waxman Act) [34]. This act amended the FD&C Act and provided two abbreviated pathways for the approval of generic drugs, including natural source products and recombinant proteins.

Section 505(b)(2) of the Hatch-Waxman Act eliminated the necessity of the generic competitor to duplicate all of the preclinical and clinical studies performed by the innovator for drug approval. This allowed the direct comparison of the generic drug with the innovator product already approved for the same indication while using abbreviated clinical trials of 3 to 6 months in duration to demonstrate comparability. The second abbreviated pathway as outlined in Section 505( j) sets forth the process by which the producer of a generic drug that is identical to a previously approved innovator product can file an Abbreviated New Drug Application (ANDA) to seek FDA approval. An ANDA allows the applicant to rely on the FDA's previous finding of safety and efficacy for the already approved drug; the FDA can request only bioavailability studies as supportive data. These allowances for an ANDA application and ultimate approval were tied to a couple of assumptions. The first assumption was that the generic drugs would be exactly the same as the innovator drug. The FDA instituted a policy that the bioavailability of the generic drug needs to be within $\pm 20\%$ of active ingredient over a period of time compared with the innovator product. For drugs with a very narrow therapeutic range, this may be problematic. The second assumption was that bioequivalence data were accurate surrogates to an innovator drug's safety and efficacy results.

The Hatch-Waxman Act does provide the innovator a period of exclusivity, so-called "data exclusivity," of up to 5 years upon approval before a generic version can enter the market. However, the act is also intended to provide a mechanism for

generic competitors to challenge the innovator's patents and provide the first in time challenger with 180 days of generic market exclusivity. To file an ANDA, the competitor must make one of four certifications: (1) the drug has not been patented, (2) the patent has expired, (3) the generic will not go on the market until the patent expires, or (4) the generic will not infringe on the patent or the patent is invalid.

In March 2010, as a part of the Patient Protection and Affordable Care Act (PPACA), or health care reform, Congress passed the Biologics Price Competition and Innovation Act (BPCI Act) of 2009, which amends Section 351 of the Public Health Service Act, creating a statutory pathway for FDA approval of follow-on biologics as "biosimilar" to or "interchangeable" with the innovator marketed biologic products [35]. The biosimilar product must have the same presumed mechanism of action, route of administration, dosage form, and potency as the innovator product. It may only be reviewed and approved for indications for which the FDA already has approved the innovator product.

The necessity for the BPCI Act is because although Section 505(b)(2) of the FD&C Act allows for the approval of generic drugs involving natural source products and recombinant proteins, the complexity of the large biopharmaceuticals makes it difficult to demonstrate that a biosimilar product is structurally identical to an already approved biopharmaceutical. Unlike SMs, for which analytical methods are adequate to ensure the sameness of a generic product to the innovator product, the size and complexity of the molecular structure of biologics preclude any exact structural comparison between the innovator and the biosimilar product. Moreover, the manufacture of recombinant proteins in living cells can result in subtle differences with respect to glycosylation and other posttranslational modifications. Even nonrecombinant proteins that are purified from their natural sources can exhibit different posttranslational modifications and have alterations in their amino acid sequences. Because the correlation between the efficacy and safety of a biopharmaceutical and its structural characteristics is rarely established, it is uncertain how these slight modifications may impact its effectiveness. In light of these factors, a follow-on biologic cannot be expected to replicate the innovator product precisely; therefore, these molecules are referred to as *biosimilars*. A biosimilar product is defined as one that is "highly similar" to the reference product notwithstanding minor differences in clinically inactive components and for which there are no clinically meaningful differences between the biological product and the reference product in terms of safety, purity, and potency of the product [36].

Under the BPCI Act, biosimilars also have the opportunity to meet a higher standard of similarity to a reference product, "interchangeability," reflecting an FDA assessment that pharmacists can make substitutions between biologics without the prescriber's intervention. A biologic will be considered interchangeable with a reference product if the developer demonstrates that it can be expected to produce the same clinical result in any given patient and that the risk associated with alternating or switching between the two products is not greater than that involved in continuing to use the reference product.

In response to the BPCI Act, the FDA has recently issued draft guidelines to define the approval process and requirements for biosimilars [37–39]. In these draft

guidelines, the FDA is advocating a stepwise approach to demonstrate biosimilarity. The first step relies on extensive comparative analytical data to the reference product to set the stage for the clinical development requirements. The more robust the analytical data demonstrating comparability to the reference product, the potential for a more targeted, streamlined clinical development program. The next step would involve consideration as to the toxicity studies that should be conducted to support biosimilarity. To avoid large head-to-head phase 3 clinical trials, the FDA is putting an emphasis on immunogenicity and PK and PD studies to mitigate this "residual uncertainty" of the biosimilarity of the product. At a minimum, the FDA anticipates that at least one clinical study to assess immunogenicity will likely be required. In addition, a clinical trial will also be required for a biosimilar to be considered interchangeable with the reference product. In addition, postmarketing surveillance may also be a key point of emphasis for any biosimilars application.

## 1.5 BIOLOGICS: THE PAST, THE PRESENT, AND THE FUTURE

With the ongoing shift in the pharmaceutical industry from an SM-centric to a balanced portfolio with equal shares of SMs and biologics, the development of biological drugs has gained a great deal of momentum as reflected by a large number of biologics in preclinical and clinical pipelines. Most major pharmaceutical companies have now implemented sophisticated processes and infrastructures to develop biologics, particularly mAbs and other protein therapeutics.

Cutting-edge technologies have significantly impacted the field of biologics discovery and development. At the molecular level, considerable protein engineering efforts have led to the development of novel molecular scaffolds, optimized molecular functions, and enhanced drug properties. At the process level, novel technologies have resulted in an increase in screening throughput, innovative methods to generate antibody candidates, reduced cycle time of early drug discovery process, and new capabilities to tackle challenging issues.

This section discusses several major trends in the discovery and development of biologics with a focus on mAb therapeutics.

### 1.5.1 Biosimilars

By McCamish and Woollett's definition, a biosimilar is a "follow-on biologic that meets extremely high standards for comparability or similarity to the originator biologic drug that is approved for use in the same indication" [40]. Having suffered from severe loss of profits immediately after a brand-name drug comes off patent, the industry has taken a drastically different approach with generic biologics, or biosimilars. Large pharmaceutical manufacturers in addition to generic drug makers have both aggressively entered the play field. Led by Merck, pharmaceutical giants Eli Lilly, Pfizer, and several others have publicly announced their endeavor in the making of biosimilars and are actively developing pipeline portfolios. Since the approval of the first biosimilar omnitrope (recombinant human growth hormone;

Sandoz) in 2006 in Europe, a number of biosimilars have now been approved by EMEA, including two biosimilar somatropins, five biosimilar rHuEPOs (recombinant human erythropoietins), and four biosimilar filgrastims [41].

The regulatory path for approving biosimilars is emerging. The EMA has led the way and issued a series of guidelines to regulate the approval of biosimilars in Europe. In the United States, FDA has started to define the approval processes and requirements (see earlier discussion). In contrast to the approval of generic SM drugs, the regulations for biosimilars are considerably more sophisticated because of the complex nature of biologics. In addition to the demonstration of composition equivalency, for a biosimilar, the proof for biological equivalency is required. As a result, the cost for developing biosimilars is considerably higher than that for generic SMs, and their market share relative to the brand name counterpart could fall in the 30% range as opposed to 70 to 90% for generic SMs (http://www.gabionline.net/Biosimilars/Research/How-profitable-will-biosimilars-be). In the coming years, we will learn much more about the regulations for biosimilar approval, the safety profiles of marketed biosimilars, the market shares relative to their brand-name counterparts, and the competitive landscape composed of both large pharmaceutical and generic drug makers.

### 1.5.2 Novel Scaffolds

One actively explored area in protein therapeutic discovery is the development of novel scaffolds that demonstrate unique and potentially superior features as compared with the established scaffolds best represented by mAbs. Novel molecular scaffolds from fibronectin-based scaffold to camelid nanobodies have been incepted first in academia more than a decade ago [42,43]. A myriad of biotechnology companies have devoted their efforts to transforming novel scaffolds into drug discovery platforms. A key challenge is to endow these novel scaffolds with drug-like attributes comparable to the well-established mAb-based scaffold. Although molecules derived from many novel scaffolds exhibit extraordinarily high target binding affinity and specificity, it is not an easy task for these molecules to achieve long *in vivo* half-lives, low immunogenicity, and good manufacturability, which are the drug-like features associated with mAbs that make them such a successful class of therapeutics. Despite these challenges, the biologics field has not been deterred to invest in the development of novel scaffolds [44]. Over the next 5 to 10 years the industry may see the maturation of some of these novel scaffold-based drugs coming onto the market. It is likely that mAbs will remain a formidable mainstream scaffold with novel scaffold-based proteins fulfilling niche applications.

Antibody–drug conjugates (ADCs) are becoming a promising new class of antibody variants for cancer treatment. An ADC is a therapeutic molecule consisting of an antibody conjugated to a toxin. The antibody functions as a targeting vehicle via its specific binding to a tumor cell surface antigen and brings the toxin to the targeted cancer cell. After the ADC is internalized by the targeted cancer cell, the toxin becomes dissociated from the antibody and subsequently leads to cell killing [45]. With the recent FDA approval of the first ADC brentuximab vedotin in 2011 and

promising data on Genentech's T-DM1 in late-stage development, there is a lot of excitement in the field to pursue this class of antibody-based therapeutics to effectively kill both solid tumor and hematologic cancer cells [46,47].

Although presently still in development, combinatorial biologics therapy may become an important treatment strategy in the future. Human diseases are generally complex in nature, and intervention of more than one molecular target and pathway is often required for successful treatment. For example, most cancers result from mutations in a large number of genes that cause dysregulation in both growth-inhibitory as well as growth-promoting pathways. In the clinic, it is already a common practice to treat patients with combinatorial therapies, and many cancer trials testing a novel biologic drug are done in combination with anticancer SM drugs. For many inflammatory diseases such as rheumatoid arthritis and inflammatory bowel disease, inhibiting one cytokine may not put a potent brake on a raging disease triggered by a multicytokine storm and simultaneous inhibition of different cytokines and their receptors may be required to manifest clinical efficacy.

Currently, there are two main approaches for combinatorial protein therapies. A multifunctional antibody (often referred to as bispecific antibody) combines two antigen-binding domains in a single molecule capable of simultaneously binding to and modulating the functions of two different molecular targets. Currently, a "trifunctional" bispecific antibody, catumaxomab, is a drug marketed in Europe for the treatment of malignant ascites. The "trifunction" refers to the simultaneous binding to EpCAM expressed on tumor cells, CD3 expressed on T cells, and Fc binding to FcγR on accessory immune cells [48]. The challenge for developing a multifunctional antibody arises from the difficulty to manufacture such an extensively engineered molecule, which often exhibits issues such as low expression levels, insolubility at high concentration, and high propensity to aggregation.

The second approach for combinatorial protein therapy is to apply a cocktail of two or more mAbs. Symphogen is one of the pioneers in this approach and has several therapeutic antibody combinations in the pipeline. The most complex one, rozrolimupab for the treatment of idiopathic thrombocytopenic purpura, consists of 25 IgG1 antibodies in one mixture [49]. A key challenge of developing therapeutic antibody mixtures is an unclear regulatory path. In theory, both the individual components and the combination in the antibody cocktail need to be proven safe and efficacious in clinical trials. This scenario would require large, complex, and costly clinical trials and could be cost prohibitive.

Even with many formidable obstacles, progress continues to be made developing combinatorial biologics. We expect this field to overcome some of these hurdles in the coming years to deliver novel antibody-based therapeutics and treatment methods into the clinic.

### 1.5.3 Drug Delivery

The delivery of protein-based biologics is an actively investigated area in the pharmaceutical industry. Unlike SM drugs, which are primarily delivered orally as tablets or capsules, the delivery of protein-based biologics is largely limited to

parenteral administration. Nasal and local delivery methods have also been applied in some cases. However, oral delivery remains largely infeasible and represents the holy grail of the field. Many efforts are under way, including novel nanoparticle formulation and the development of small and highly stable scaffolds that may survive trafficking through the digestive tracks to reach circulation. However, it will likely take years before oral delivery of protein drugs becomes a reality.

Another delivery challenge is for biologics to cross BBB to reach therapeutic targets that reside in the CNS. A number of biotechnology companies are applying novel technologies to this area using both targeted delivery and nanoparticle-based method to deliver biologics across BBB. So far the success has been limited.

### 1.5.4 Immunogenicity

Because of the complex multifactorial causes of immunogenic response in patients to protein drugs, it is extremely difficult to accurately predict the immunogenicity of a therapeutic candidate. It is possible, however, to assess the potential immunogenicity risks associated with a candidate molecule during preclinical development and devise clinical plans that monitor and manage the antidrug response in human patients. Because this is a critical safety aspect of biologic drugs, the field will strive to unravel the immunologic basis of immunogenicity at the molecular, cellular, and physiological levels, as well as design and implement new testing methods to accurately measure the clinical antidrug response.

### 1.5.5 Streamline the Drug Discovery and Development Process

Cutting-edge technologies are constantly applied to streamline both early drug discovery and manufacturing processes for the development of biologics. In discovery, automation is routinely implemented at various stages of the workflow to reduce manual labor and increase the throughput of various screening steps. In manufacturing, there is a strong trend toward switching from the traditional permanent bioreactors to disposable bioreactors. Meanwhile, production of extraordinarily high levels of therapeutic proteins using optimized protein expression systems has become a reality. These technology innovations will ultimately lead to a significant cost reduction in making biologics, ultimately improving the commercial viability for this class of drugs.

## 1.6 CONCLUSION

An industrial focus on the development of biologic drugs, including both new therapeutic entities and biosimilars, will continue for years. Currently, a sophisticated process built on the foundation of cutting-edge technologies has been put in place to support biologic drug development. Technological advancement will continue to make a major impact to this field, shaping both the process and the therapeutic entity. There are similarities as well as differences in the development of SM and biologic drugs. A

balanced portfolio with an equal share of both SM drugs and biologics is becoming a typical business strategy for large pharmaceutical companies.

# Nonclinical Safety Assessment of Biologics, Including Vaccines

LIANGBIAO GEORGE HU and DAVID W. CLARKE

## 2.1 INTRODUCTION

There are several definitions as to what constitutes a biopharmaceutical. The official Food and Drug Administration (FDA) definition of "biological products" or "biologics" can be summarized as "any virus, therapeutic serum, toxin, antitoxin or analogous product applicable to the prevention, treatment or cure of diseases or injuries of man" as codified in 21 CFR 600.3 [1]. The European Union regulations define "biological medicinal products" as "a protein or nucleic acid–based pharmaceutical substance used for therapeutic or *in vivo* diagnostic purposes, which is produced by means other than direct extraction from a native (non-engineered) biological source" [1].

The definition of a biotechnology-derived product (biologics) has changed over time. Biologics can generally be divided into various classes, which include recombinant proteins, monoclonal antibodies (mAbs), vaccines, gene transfer products, and somatic cell therapy products. However, some other non–biotechnology-derived biologics, including synthetic peptides and synthetic oligonucleotide-based technologies produced by chemical synthesis, conventional biologics, and tissue products, may also be classified as biologics [2,3].

For any pharmaceutical, either chemically synthesized small molecules (SMs) or biologics, the regulatory expectations for nonclinical testing is outlined in various regulatory documents [4]. The initial standardized international guidance was put forth by the International Conference on Harmonization (ICH), which dealt directly with the nonclinical testing of biopharmaceuticals (ICH S6, 1996) [5]. Revised regulatory guidances ICH M3(R2) [6], ICH S6(R1) [7], and ICH S9 [8] expanded on the guidelines for biotechnology-derived products.

Biologics have many properties that are different from traditional chemically synthesized SMs. Biologics are generally large molecules or heterogenic mixture of large molecules; have complex physicochemical characteristics; are heat sensitive, which makes them not easily characterized; often display species specificity and pleiotropism in their pharmacologic effects; and are often immunogenic. SMs are

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*,
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

usually synthetic, organic compounds with well-defined structures and relative stability. Biologics generally have high selectivity and specificity for their targets, significantly minimizing the risk of off-target adverse effects, except antibody drug conjugate (to be discussed later) and are often catabolized to amino acids with limited metabolite-related toxicities. In contrast, SM drugs have high potential for off-target activity, and such toxicity is often mediated through metabolism by liver enzymes, such as cytochrome P450. Whereas biologics are usually administered by the parenteral route (i.e., intravenous [IV], subcutaneous [SC], or intramuscular [IM]), SM drugs are often able to be administered orally. Unlike most SM drugs with a short half-life (usually hours), many biologics, particularly those with a large molecular weight, can have a long half-life (up to a few days or weeks), which allows weekly to monthly dosing clinically. Biologics also have some unique advantages in that targets presumed nontractable by chemical means might be suitable for biologics, which creates new opportunities to manipulate the well-defined functional domain(s) of a biologic to improve its safety and efficacy, such as bispecific mAbs and vaccines [4,9,10].

The increase in the number and vast array of biologics in development has been paralleled by innovations in bioengineering and production technologies that make industrial-scale manufacture of biotechnology-derived therapeutic agents possible. Nonclinical safety testing programs must be rationally designed with a strong scientific understanding of the product, including its method of manufacture, purity, sequence, structure, species specificity, pharmacologic and immunologic effects, and intended clinical use. In addition, a firm understanding of the regulatory requirements for a particular product type, such as mAb, antibody–drug conjugates (ADCs), or vaccine will ensure that the most appropriate and regulatory-compliant test systems are used to achieve the best chance of gaining regulatory approval for clinical testing and marketing authorization in the shortest possible research and development cycle [11–13].

Vaccines represent a unique class of biopharmaceutical products. Two major classes of vaccines have been approved or are under development: prophylactic and therapeutic (refer to other chapters in this book). Requirements for nonclinical toxicity studies depend on the vaccine's potential antigenic target, risk-to-benefit consideration, target population, available clinical data from relevant products, product features, and the availability of animal models [2,14–16]. In general, a dialog with the regulatory agencies would help manufacturers and vaccine developers clarify what preclinical toxicology studies are needed, approaches to study design, and the extent of nonclinical toxicology study documentation required before initiation of clinical trials [17].

An ADC is a hybrid that carries both properties of a biologic (mAb portion) and an SM (linker and payload). The ADC concept is based on combining the strengths of the individual large and SMs while eliminating the weaknesses of each individual approach. A well-designed ADC should minimize the systemic toxicity of the free drug (payload) by selectively delivering it to the target cells. The mAb portion of the ADC would bind to the target protein on the cell surface, which in turn triggers the internalization of the antibody–antigen complex. After release within the endosome or lysosome, the payload or linker payload would exert cytotoxic effects on the

cells expressing the target. The mAb may in itself have biological activity; however, this is not a strict requirement for an ADC. To date, the majority of ADCs in development are for cancer indications, and the most common drugs or payloads include tubulin inhibitors, such as auristatins and maytansinoids; compounds that induce DNA double strand break, such as calicheamicin; and DNA minor groove binder alkylators, such as duocarmycin. The payloads are generally attached to the mAb via a cleavable linker (susceptible to acid or catalytic cleavage) or a non-cleavable linker that requires proteolytic degradation of the antibody to release the payload. A strong scientific understanding of the biology and distribution of the mAb component, the nature of the linker (cleavable vs. noncleavable) and pharmacology of the payload is critical to rationally design the nonclinical toxicity studies. A characteristic of the payloads used in ADCs is that they are extremely potent (nM $EC_{50}$s) and therefore are extremely toxic, which can lead to toxicity in cells that express the target. Therefore, it is critical to identify a target that is expressed primarily on tumor cells to limit the toxicity in nontumor cells. So far, the clinical data generated with the leading ADC platforms indicate that their toxicities overlap and include thrombocytopenia, neutropenia, peripheral neuropathies, and elevation in liver enzymes, which appear to be serious safety concerns. Nonclinically, in addition to the clinical observations, certain dose-dependent renal, lung, and liver changes represent serious nonclinical complications [18]. Given the differences in the mechanism of action of different payloads and the biological roles of the respective cell surface antigens, many of the dose-limiting toxicities observed clinically and nonclinically may be related to off-target toxic effects, potentially caused by binding to FcRγ or nonspecific endocytosis or pinocytosis-mediated uptake of ADCs in certain cell types. The nonspecific release of the toxic payload in bone marrow or liver might be another off-target contributor to the toxicities in these organs [19–24]. To date, there are no specific regulatory guidelines for the nonclinical safety assessment of ADCs.

The remainder of this chapter discusses nonclinical factors that need to be considered when developing a biologic with respect to both program strategy and the nonclinical evaluation of toxicity.

## 2.2 CONSIDERATIONS IN THE SELECTION OF THE ANIMAL SPECIES

### 2.2.1 General Introduction

Based on the specificity of the target for most biologics, the selection of relevant species for nonclinical studies, including toxicology studies, is a critical issue to allow accurate translation of animal data into humans. The key principle in ICH S6 (R1) for selection of a toxicology animal species is the pharmacologic relevance of the species [5,7]. ICH S6 indicates "comparisons of target sequence homology between species can be an appropriate starting point, followed by cell-based assays to make qualitative and quantitative cross-species comparisons of relative target binding affinities and receptor/ligand occupancy and kinetics. Assessments of

functional activities are also recommended" [5]. Therefore, a pharmacologically relevant species should have the following minimum properties: expression of the target protein or amino acids, the target to be recognized by the therapeutic biologics with sufficient affinity to allow the evaluation of the pharmacological activity, and a target with pharmacologic functions similar to those in humans. Also, the biologic should possess similar functional potency in humans and animals. Other factors, such as tissue distribution of the target in the selected animal species, should be comparable to that in humans.

Even though the tissue expression profile may not accurately predict the toxicity of most biologics, such as mAbs, it is critical for the selection of a relevant animal species.

Vaccines represent a unique type of biologic. In particular, prophylactic vaccines generally target infectious diseases; therefore, they may not demonstrate sequence homology with mammalian species. Unlike toxicology programs for SMs and other biologics, vaccine programs typically use a single species, which must be demonstrated to be a relevant animal model based on the immunogenicity or efficacy of the vaccine in the selected animal species. Routinely, either rats or mice (rodent species) or rabbits (nonrodent species) are used for toxicology studies. Nonhuman primates (NHPs) may be used if it is the only species that has homology with the human antigen, which often occurs with therapeutic vaccines [2,17].

### 2.2.2 Sequence Homology

The requirement of two toxicology species, one rodent and one nonrodent species, is still a standard in nonclinical toxicology programs. Based on the literature or public databases, the homology of the DNA, RNA, or amino acid sequence among the various animal species and human should be analyzed. Even though sequence similarity is not sufficient to prove a relevant species, the data may be an important factor in the selection of toxicology animal species because the sequence homology may directly correlate to the biological function of the target [9]. For example, erythropoietin (Epo) is a hematopoietic cytokine that regulates red blood cell production and has a high sequence homology across species (human Epo is 91% identical to monkey; 85% to cat and dog; and 80 to 82% to pig, sheep, mouse, and rat), which may explain the biological and immunologic cross-reactivity that has been observed in a number of species [25]. Thus, sequence analysis would be the first step in selection of relevant toxicology species.

### 2.2.3 Target Affinity, Distribution, Biology, and Biochemical Pathways

Nonclinical *in vivo* safety studies for new chemical entities (NCEs) are designed to identify a broad range of potential adverse effects that may or may not be related to the pharmacologic action of the drug. However, biological products, such as mAbs, have high target specificity, and their toxicities are usually the result of exaggerated pharmacology, which may allow for better prediction of the adverse effects, provided that the pharmacologic actions across species are similar. To define a species as

pharmacologically relevant, ideally, the target of interest should be modulated in a manner similar to that in humans, such as activation of downstream signaling pathways or effector function [26]. Therefore, a thorough review of the biological activity of the target and comparison of the expression profile of the target between human and animal species would gain substantial information in the selection of toxicology relevant species. Concerns arising from target biology–related toxicities have been highlighted by past experiences with two therapeutic mAbs, natalizumab (α4-intergrin) and TGN1412 (anti-CD28) [27,28]. Administration of TGN1412, a super-agonist mAb, in six healthy volunteers led to devastating adverse effects related to activation of T cells [29]. Natalizumab, indicated for the treatment of multiple sclerosis, was recalled from the market because it induced a rare fatal viral demyelinating disease, progressive multifocal leukoencephalopathy, in two patients [30]. It can be deduced from these examples that without a thorough understanding of the distribution and function, mAbs with immunomodulatory properties have the potential to induce unexpected toxicities.

***2.2.3.1 Target Binding and Specificity Assay*** Surface plasmon resonance–(SPR-) derived technology, Biacore assay, is well suited to carry out qualitative studies to confirm the specificity of target interactions as well as quantitative measurements for affinity, kinetics, and concentration determination. The optical biosensors characterize binding events with samples ranging from proteins, nucleic acids, and SMs to complex mixtures, lipid vesicles, viruses, bacteria, and eukaryotic cells. A small volume of analyte can be tested easily for selective binding to 2 to 400 targets simultaneously, depending on the instrument platform chosen. Therefore, Biacore assays have become one of the most favorable options for characterizing the target binding affinity and specificity of the biologics [31]. Alternatively, evaluation of antibody binding to cells by flow-activated cell sorting (FACS) is sensitive and widely used in the development of biologics. Enzyme-linked immunosorbent assay (ELISA) and other *in vitro* assays are also available and validated for binding and specificity assays. Both Biacore and FACS analysis can provide information as to whether the biologic binds to the same site as the endogenous ligand or at a different site. With both techniques, the association or disassociation rate constants can be determined to provide an understanding of the binding affinity.

***2.2.3.2 Biodistribution*** Biodistribution of the target antigen *in vivo* should be comparable between the relevant animal species and humans to allow evaluation of toxicity arising from binding to the target antigen, which is referred to as on-target toxicity. This can be accomplished through an understanding of the RNA or protein expression in various tissues. Tissue cross-reactivity studies may also provide information with respect to the distribution of the target (see Section 2.3.4.5).

***2.2.3.3 Target Functional Activity Assay*** Per ICH guideline S6, the functional aspects of a biologic binding to the target are essential to determine if the selected species is pharmacologically relevant. Cell lines and primary cell cultures have

been used to determine the direct effects on cellular phenotype, the live cell activities, such as cytokine and chemokine release and proliferation induced by the biologics. The data may be further used to predict specific aspects of *in vivo* activities and assess quantitatively the relative sensitivity of various species including human. For example, CD28, an agonist mAb, is involved in T-cell proliferation [32], an *in vitro* cell-based assay can be used to determine if the therapeutic mAb induces the desired pharmacologic effects. In contrast, an antagonist mAb (e.g., Remicade) would functionally block the effects of administered human tumor necrosis factor α (TNF-α) in an *in vitro* cell-based assay [33]. However, an *in vitro* assay may not be readily available for all targets and may require extensive characterization of the target to understand the functional implications of binding to the target.

### 2.2.4 Use of Genetically Altered Rodents and Surrogate Antibodies

If it is not possible to identify a relevant species for toxicologic evaluations, alternative toxicology models might be required for a valid toxicology study [34].

***2.2.4.1 Genetically Altered Rodent Model*** Transgenic models that express the appropriate human transgene, such as knock-out or human knock-in mouse models, enable biologics to be tested on the human target antigen. An example is keliximab, a primatized anti-CD4 mAb. The anti-CD4 mAb, originally developed for the treatment of asthma and rheumatoid arthritis, only binds to human and chimpanzee CD4. A humanized transgenic mouse expressing human CD4 was used for pharmacokinetic (PK) and pharmacodynamic (PD) studies, single- and repeat-dose toxicity studies, and host defense and to address the safety concerns of anti-CD4 immunosuppression as an adverse side effect. However, there are disadvantages of using transgenic mouse model for biologics. If the target does not exist inherently in a rodent, it is logical to extrapolate that the target pathway might not exist; therefore, binding to the target may not have the same functional effect. Furthermore, the breeding of the transgenic mouse line is potentially challenging, such as the expression and retention of the transgene in the colony [9,35,36].

***2.2.4.2 Use of Surrogate Antibodies for Testing*** An alternative may be to raise a surrogate mAb against the homologous antigen present in a rodent. The surrogate protein is not the therapeutic biologic; however, it may be used to evaluate the pharmacologic or toxicologic effects of the pharmacologic mechanism in a rodent that is considered comparable to that of the biologic in human. The transgenic mouse and surrogate antibodies are more acceptable when the only other species that is relevant to the testing drug candidate is chimpanzees. To date, surrogate antibodies have been used frequently in reproductive toxicity studies. For example, infliximab, a humanized anti-TNF mAb, only cross-reacts with human and chimpanzee. The surrogate anti-TNF mAb was successfully used to evaluate single-dose escalation studies, a 6-month toxicity study, and reproductive toxicity studies. The disadvantage of surrogate antibodies represents a parallel development program, which is very

expensive and might not necessarily satisfy all of the regulatory concerns because the clinical candidate is not being evaluated [9,37,38].

In general, if one pharmacologically relevant species is available and used as the primary toxicology species, studies in a second species with a surrogate or homologous product are not considered to add further value for risk assessment and are not recommended [7].

### 2.2.5 Use of Animal Models of Disease

For biologics that are used to correct an excess or deficiency of a protein in a disease condition, it may not be possible to evaluate the safety in normal animals because it may lead to an unacceptable exaggeration of the pharmacology. In this case, understanding the safety in an animal model of disease, if available and appropriate, should be considered. For example, a biotherapeutic drug used to reduce calcium levels under conditions of extreme hypercalcemia can result in hypocalcemia or toxicity in a normal healthy animal.

Because of the nature of the biologics, many drug products (DPs) only cross-react and have pharmacologically activity in primates. A disease model may not be available in primates. In this case, a homologous protein could be used if available. Transgenic or KO mice may also be challenged with the disease to understand safety issues in a condition that more closely mimics the clinical situation [9,36]. In general, lack of historic control data, validation of the animal model, and uncertainty around the regulatory agencies are the major obstacles in using this approach.

## 2.3 CONSIDERATIONS FOR THE NONCLINICAL SAFETY EVALUATION

The nonclinical safety evaluation of a biologic is not substantively different from any other programs. A number of guidance documents are available to assist. The most critical one is ICH S6 guideline with respect to the types of studies, and the ICH M3 guideline provides guidance on the general timing of the studies.

The first steps in developing a nonclinical safety evaluation plan for a new biopharmaceutical are to understand the product attributes, including the biochemical and biophysical characteristics and pharmacologic activity of the product and the target. Studies should be conducted only after the relevant species have been properly identified (see Section 2.2) and can be conducted in rodents (typically rats) and NHPs (typically cynomolgus monkeys) or in the NHP only, depending on which species are considered relevant. Studies should not be conducted in a nonpharmacologically relevant species; exception to this may be with the ADCs, in which studies in a nonpharmacologically relevant species may provide information on the toxicity of the payload portion of the molecule.

In some cases, toxicity endpoints can be incorporated into a discovery pharmacology study, as appropriate. If the highest dose used in a pharmacology study adequately characterizes the toxicity profile of the molecule, it may be acceptable to

use these data to support the first in human– (FIH-) enabling studies rather than conducting a stand-alone exploratory toxicity study.

Numerous regulatory guidelines specifically detail the requirements of nonclinical safety evaluations. Among all ICH guidelines, ICH document S6: Preclinical Safety Evaluation of Biotechnology-Derived Pharmaceuticals (CPMP/ICH/302/95) [5,7] is the key guideline for all biological product development. For mAbs, the Center for Biologics Evaluation and Research (CBER) published "Point to Consider in the Manufacture and Testing of Monoclonal Antibody Products for Human Use, 1997." For vaccines, there are a few guidelines specifying different aspects of vaccine development, such as Evaluation of New Adjuvants in Vaccines (CPMP/BWP/6622/02) [39], reproductive toxicology studies for preventive vaccines for infectious disease indications (CBER, FDA, 2006) [40], plasmid DNA vaccines for preventive infectious disease indication (CBER, FDA, 2007) [41], pharmaceutical and biological aspects of combined vaccines (CPMP/BWP/477/98) [42], preclinical pharmacologic and toxicologic testing of vaccines (CPMP/SWP/465/95) [16], and WHO guidelines on nonclinical evaluation of vaccines [15].

In general, the safety assessment programs should normally include two pharmacologically relevant species. However, for many biological products, one species can be used if no other relevant species can be identified. For example, many mAbs do not cross-react with rodents, so a single species is usually sufficient. For testing mAbs, the primate is usually the species of choice for humanized or human mAbs; for vaccines, often rodents or rabbits are often used; and for gene–cell therapy vectors, rodents are the most common species. The ADCs are hybrid of SM and biologics; therefore, even though most humanized mAb portion only cross-reacts in NHPs, the toxicology studies are typically conducted in two species, rodents (typically rats) and nonrodents (typically NHPs).

### 2.3.1 Route of Administration

The route of administration for biologics is dependent on the intended clinical regimen. The oral route of administration is generally not applicable for a biologic. Most anticancer biologics, including mAbs and ADCs, especially for late stage cancer, are clinically delivered by the IV route. Most biologics used for chronic indications are typically administered by the SC route. For vaccines, historically, the IM, SC, and intradermal routes have been used, although the oral and intranasal routes are now actively exploited. Nonclinical studies should use the intended clinical route of administration when practicable.

### 2.3.2 Selection of Doses for Toxicity Studies

As outlined in ICH S6, a rationale for dose selection should take into account the exposure–response relationship. Pharmacology and PK and PD information can be used to assist in dose selection. Dose selection in all studies should be based on exposure– (Area under the concentration time curve (AUC), efficacious concentration ($C_{eff}$), etc.) response relationships rather than dose only (mg/kg) because

the exposure or response at a specific dose in one species may not directly translate to a similar exposure and response at the same dose in another species or human.

There is no scientific information to support that high doses of protein cannot be administered to animals for long periods of time. The concept of "protein burden toxicity" has not been proven, and there are examples in which large doses of protein have been administered chronically with no associated toxicity. Therefore, there is currently no rationale to limit the high dose based on these arguments. The most recent revision of the ICH S6 provides some guidance on the selection of the high dose in that one needs to consider: (1) a dose (exposure) that provides the maximum intended pharmacologic effect and (2) a dose that provides an approximately 10-fold higher exposure than the maximum dose exposure in the clinic (note: this is *not* the minimum efficacious dose). The higher level of these two doses should be selected as the high dose of the repeat dose studies unless scientific data support a lower dose [7]. A relatively large difference in binding affinity or *in vitro* potency might suggest a need for higher doses in nonclinical studies. In the event that toxicities cannot be demonstrated at the doses selected using this approach, then traditional toxicity studies with higher multiples of human dose levels are unlikely to provide additional useful information. However, a limit dose approach in alignment with ICH M3 and similar to that used for SMs can be used as appropriate.

When *in vivo/ex vivo* PD endpoints are not available, the high dose selection can be based on PK data and available *in vitro* binding or pharmacology data.

Many companies have established default dose levels for a new biologics that achieve these objectives. The highest dose is often defaulted to 100 mg/kg in NHPs and 200 mg/kg in rodents, with the exception of ADCs, oligos, and vaccines. For ADCs, the calculated high dose levels using the assumptions described above may be far over its maximum tolerated dose. Therefore, a lower dose should be used to ensure the success of the toxicology studies [4]. For vaccines, it is generally acceptable to set the high dose to be equal to the maximum human clinical dose [15].

### 2.3.3 Safety Pharmacology

In addition to the ICH S6 [5], S6(R1) [7], and S9 [8] guidances, the ICH S7a [43] and ICH S7b [44] represent specific guidances on Safety Pharmacology studies for human pharmaceuticals. In accordance with regulatory requirements, assessments of cardiovascular (CV), central nervous system (CNS), and pulmonary function must be performed before FIH. Some biologics carry a higher level of risk for safety pharmacology issues based on target tissue expression, mechanism of action, therapeutic indication, or patient population (e.g., those for diabetes, CV, or metabolic indications or targets that are expressed on cardiac tissues). However, for most standard biopharmaceuticals it is appropriate to incorporate the evaluations into the single-dose or repeat-dose toxicity studies. When there is a concern for an effect on the CV system, a stand-alone study is likely warranted. However, the standard Latin-square design used with SMs may not be applicable because of both the long half-life and the possibility for formation of antidrug antibodies (ADAs) [45]. Rodent telemetry may be used for any biologics with a predefined CV risk and

that have pharmacologic activity in rodents (rats or mice). These studies could incorporate echocardiography if there is an elevated concern for modulation of cardiac structure (e.g., left ventricular hypertrophy) or function (percent ejection fraction or contractility); however, the biologic must be biologically active in rodents (rats or mice). If there is no biological activity in the rodent, then NHP telemetry studies (heart rate, blood pressure, electrocardiography [ECG]) may be used for early CV assessment. For biologics with no known CV risk, the collection and evaluation of basic CV endpoints (surface lead ECG in chair-restrained animals) as part of the FIH-enabling Good Laboratory Practice (GLP) NHP toxicity study is sufficient to meet regulatory guidelines [46]. It is generally not advisable to collect CV endpoints in rodent FIH-enabling GLP toxicity studies.

The *in vitro* human ether-a-go-go (hERG) assay is generally not required for mAbs, vaccines, therapeutic proteins, and therapeutic peptides because of the low propensity for binding of biologics to the potassium ion channel.

Certain biologics carry a greater risk for CNS safety issues, such as those being developed for neurologic or psychiatric indications or pain and indications in which the blood–brain barrier (BBB) may be compromised (e.g., diabetes, oncology, CNS, and peripheral inflammatory disorders) or whose targets are expressed in the central or peripheral nervous system. For biologics that fit these categories, it may be necessary to include detailed observations in the form of a neurologic examination (for NHPs) or Functional Observational Battery or Irwin Test (for rodents) in single-dose or repeat-dose studies. For biologics with little known CNS risk, the evaluation of CNS endpoints, including body temperature measurements, obtained as appropriately timed clinical observations in FIH-enabling studies in rodents or nonrodent GLP toxicity studies, should be sufficient to satisfy regulatory requirements.

Likewise, evaluation of the effect of a biologic on the respiratory system can be achieved via addition of pulmonary measurements (e.g., respiratory rate) to the FIH-enabling nonrodent GLP toxicity study. Stand-alone respiratory safety pharmacology studies are generally not performed unless there is a strong scientific justification. If both the rodent and the NHP are appropriate species for the toxicology evaluation, adding respiratory measurements to the rodent study allows for the collection of data in a species with a more defined historical database.

In general, gastrointestinal and renal assessments are not considered necessary (either as stand-alone or incorporated into toxicity studies) unless there is a perceived risk of serious concern. In such cases, specialized assessments may be designed either as additions to toxicity studies or as separate stand-alone studies.

### 2.3.4 General Toxicology Studies

In general, toxicology studies should be conducted by the same route and schedule of administration as proposed in human subjects. To gain a successful approval from regulatory agencies, a complete general toxicology package should include, but is not limited to, the following *in vivo* toxicology studies: (1) single-dose toxicity study, (2) repeat-dose toxicity studies, (3) developmental and reproductive toxicity studies,

and (4) genotoxicity and carcinogenicity studies. In addition, ICH M3R2, ICH S6, and ICH S9 provide comprehensive reviews on the duration of nonclinical studies relative to clinical development [5–8]. Safety evaluation programs should normally include two relevant species. However, although two species may be necessary to characterize toxicity in short-term studies, it may be possible to justify the use of only one species for subsequent long-term toxicity studies (e.g., if the toxicity profile in the two species is comparable in the short term). If the NHP is the only relevant species, it is generally recommended to use mature NHPs (typically cynomolgus monkeys). Mature NHPs may provide useful information for fertility and reproductive toxicity (refer to relevant sections).

***2.3.4.1 Single-Dose Toxicity Studies*** Single-dose toxicity studies with biologics may, in theory, be useful in describing the relationship between dose and systemic and local effects and in defining dose levels for use in repeat-dose studies but are not intended to define the no-observed-adverse-event level (NOAEL). These studies should be conducted in a pharmacologically relevant species, rodent (typically rat) and NHPs (typically cynomolgus monkeys). For most biologics, for which NHP is the only relevant species, one species should be sufficient. ADCs represent a somewhat unique situation in that they are a hybrid of both SM and mAb. As such, a single- or two-dose non-GLP toxicity study in rodents (typically rats), in addition to NHPs, is recommended to screen the off-target related toxicities. For prophylactic vaccines, single-dose toxicity studies are not usually conducted.

Single-dose toxicity information may be obtained from pharmacology and PK studies provided they are conducted using the relevant species and appropriate dose level to characterize the toxicity profile.

Typically, single-dose toxicity studies are conducted at the early phase of the drug development using research-grade drug substance (DS). The resource constraints, such as the amount of available DS, may effectively limit the high dose selection. These studies are generally not conducted according to GLPs [6].

For single-dose toxicity studies in NHP, animals should be observed for at least 2 weeks after dosing, and blood samples for measurements of plasma drug concentrations should be included. If there is a cause for concern, animals can be necropsied, and a limited major organ panel and suspected target organs should be examined microscopically. The panel should include the liver, lung, kidneys, spleen, bone or bone marrow, eyes, heart, testis or ovaries, and injection site. Based on the type of biological modality, the dose level and study duration should be adjusted to obtain reliable data to allow for dose selection for longer repeat dose studies. If the biologic cross-reacts with rodents, then a 2-week observation period with serum collection for drug level determinations followed by a necropsy may be appropriate. Microscopic evaluations should consist of the major organs, as outlined for nonrodents. Collection of blood samples for immunogenicity analysis may be helpful but not essential.

If a biologic is to be administered only once in the clinic, there may be value in conducting a more detailed GLP single-dose toxicity study, as outlined in the ICH M3(R2) [6] to support dosing in early clinical trials.

***2.3.4.2 Repeat-Dose Toxicity Studies*** Many biologics are intended for repeat dosing in the clinic, and hence repeat-dose toxicity studies are usually required to support drug safety for the first human clinical trial. The DP used for repeat-dose toxicity studies should be highly comparable to, if not the same as, the DP to be used for studies in human in terms of manufacturing processes and analytical quality. There are likely to be more than one repeat-dose study of different durations conducted during the development of biologics. The duration of dosing in these studies should be sufficient to support clinical development as outlined in ICH S6 and ICH M3(R2) [5–7]. The longest duration of dosing is generally 6 months for chronic toxicology studies to support biological product registration except for late stage cancer indications in which a 3-month toxicology study in duration is considered adequate [6,8,34,47].

An exception to this is for vaccines, in which the number of doses administered generally exceeds maximum clinical doses ($N$) by at least one administration ($N+1$). The vaccine dosing frequency should be sufficient to induce the desired immune response, typically biweekly, and the route of administration is typically IM. A subset of animals is terminated 3 days after the last dose, and the remaining animals approximately 28 days after the last dose. With vaccines it is strongly recommended to conduct a pre–investigational new drug meeting with CBER reviewers to discuss nonclinical studies, clinical study designs, data requirements, and other scientific issues that need resolution before the initiation of clinical trials [17].

The repeat-dose toxicity studies are usually conducted according to GLP regulations. If appropriate, the studies should be conducted using two relevant species, rodents (typically rats) and nonrodents (typically NHPs). Typically, animals are dosed once every half-life for at least four doses with an additional dose 2 to 3 days before termination. Analysis may include the appearance of the injection site, clinical signs, hematology, clinical chemistry, urinalysis, and macroscopic and microscopic examination of all organs. For the ADC programs, animals are typically given two to four doses either every other week or every 3 weeks depending on the proposed clinical dosing frequency. Animals in the dosing phase are terminated for pathology analysis 3 days after the last dose.

The repeat-dose toxicity studies typically include three dosing groups and a vehicle control group, and doses should be selected to cover the range from a no effect level to one that induces toxicity. However, dose selection for a biologic can be complicated in that all proposed dose levels may exceed a maximum pharmacologically active dose (see Section 2.3.2). The low dose should represent a level that provides an equivalent exposure to at least an efficacious exposure and the mid-dose is included for further characterization the dose response of any observed effect [6].

In many development programs, the definitive clinical route of administration has not been established when the repeat-dose toxicity studies are initiated. Therefore, an additional high-dose group using alternative route of administration may be added to the study as the fourth dosing group. In this way, the repeat dose study would cover two potential routes of administration in clinic. In addition, some safety pharmacology endpoints (e.g., ECG if the NHP is selected), samples for ADA and TK and immunotoxicology should be included in the study [48].

A recovery period should be included to examine the reversibility of any toxic effects observed during the dosing phase studies. However, the evaluation of recovery is not warranted if there are no adverse effects at the end of the dosing period or sufficient scientific justification can be provided. The nondosing recovery period is not designed for the assessment of delayed toxicity or solely for the determination of immunogenicity. Recovery animals are usually added to the high-dose and control groups unless a high death rate is expected at the high dose. The recovery period should be equal to 5 half-lives [6,11,32]. As a default model, for mAbs and ADCs, an 8-week recovery period is usually sufficient; for vaccines, it is generally 2-4 weeks. However, for certain biologics, the recovery period may need to be 3 months or longer in order to evaluate the reversal of target organ toxicity (e.g. testicular changes) or prolonged PD effects. Unless there are specific toxicity concerns, histopathology assessment of the target organs is sufficient to determine the reversibility in recovery animals. A complete reversal of toxic effects is not necessary as per ICH guidelines S6. An extended recovery period would not add additional value.

#### *2.3.4.3 Reproductive Toxicity*

*Considerations of Species Selection for Reproductive Toxicity* A number of recent reviews have discussed considerations for assessing the developmental and reproductive toxicity potential of biologics [49–51]. The principles of developmental and reproductive toxicity studies for biologics are not different from those for other SMs; however, biologics pose some unique challenges. The need to conduct developmental and reproductive toxicity studies is dependent on the product, clinical indication, and patient population [5–7]. Because biologics tend to be highly specific for their target in the human body, they often show limited cross-reactivity with the traditional species used for reproductive studies (i.e., rats and rabbits).

Although traditional SMs (molecular weight $<1000$ daltons) readily diffuse across membranes and the placenta, biologics do not and therefore have limited access to the conceptus and are not likely to interact with DNA or other intracellular organelles. However, there are specific mechanisms for transporting particular classes of large molecules across the membranes, including the placenta. An example is the transport of antibodies across the placenta by endocytosis via the FC receptor [52]. Immunoglobulin G (IgG) is the predominant means of fetal immunity, and it is transported across the placenta. This transport happens in a linear fashion as the pregnancy progresses, with the largest amount transferred in the third trimester. Preferential transport occurs for IgG1 followed by IgG4 and IgG3 with IgG2 being the least detected [53,54].

The choice of the species to be used must be carefully determined. Although many biologics are less cross-reactive with any of the standard species (rats, rabbits) used for reproductive toxicity studies compared with NHPs, ICH S6 provides some latitude in that it only indicates the studies should be conducted in a relevant species, not necessarily the most relevant species. Although NHPs may be physiologically similar to humans, it is extremely difficult to perform reproductive toxicity studies in

NHPs because of the high rate of spontaneous abortion (up to 28%), low fertility, few offspring, and long gestation [9,34]. As a general principle, when the clinical candidate is pharmacologically active in rodents and rabbits, these species should be used for reproductive toxicity studies unless there is a scientific reason to use an NHP.

The use of traditional animal models has many advantages in that the study designs, methods, and historical data are readily available. However, if the NHP is the only relevant species, one needs to consider their use. A large historical database exists for both rhesus and cynomolgus monkeys, and many contract research organizations have experience with both strains. Cynomolgus monkeys are more appropriate for reproductive toxicity testing than rhesus monkeys because the latter are seasonal breeders, which makes the toxicity testing especially difficult [25]. However, compared with rodents, in which antibodies can cross the placenta throughout gestation, in human and NHPs, transfer of antibodies occurs primarily during the latter part of pregnancy (i.e., after organogenesis). This could lead to teratogenic effects being noted in rodents but not in NHPs or humans. Several recent papers have dealt with many of the issues involved with conducting reproductive toxicity studies in NHPs [49,50].

An alternative reproductive toxicology strategy may be used in place of NHPs if a sound scientific justification can be provided. As discussed in the previous sections, use of transgenic mice expressing the human target or use of a homologous protein in a species expressing an analogous copy of the human target can be considered when the biologic only cross-reacts with humans and chimpanzees [9]. The use of genetically modified mice as a tool for evaluating developmental and reproductive toxicity is gaining some acceptance for those products where bioactivity is limited to humans and NHPs. The use of these models may allow for the identification of the reproductive hazard associated with the biologic. For example, a knock-out animal that was viable and without discernible development issues may support that a biologic with antagonist activity may be of limited hazard with respect to reproductive and developmental effects.

*Fertility* When a clinical candidate is only pharmacologically active in the NHP, the potential effects on male and female fertility can be assessed by standard histopathology evaluations, organ weights, and assessment of menstrual cyclicity in repeat-dose toxicity studies for at least 3 months using sexually mature NHPs. This study can be included in the repeat-dose toxicity study protocol. However, one must ensure that sexually mature animals are available and used in these studies. If there are specific concerns over reproductive toxicity, sperm assessment, and reproductive hormone analysis may be included in the study protocol.

If rodents are a relevant species, a standard fertility toxicity study using the protocols consistent with those for SMs is appropriate.

*Embryo–Fetal Development and Pre- and Postnatal Development* The objective of the developmental toxicity assessment is to provide safety information on the risk of exposure during pregnancy, pre- and postnatal development. Biological candidates

with Fc-containing modalities, such as mAbs, do have the capability of crossing the placenta with a species-specific profile over the course of gestation [52]. Because of the differences in placental transfer across species, the information on embryo–fetal exposure in nonclinical studies would be important for human risk assessment.

For both SM and biological candidates, the most preferred toxicology species for embryo–fetal development (EFD) studies are rabbits and rodents. If the biological candidate molecule is pharmacologically active in both rodents and rabbits, both species should be used to evaluate for effects on EFD. However, one species should be acceptable for EFD evaluation if the species selection is scientifically justified or if lethality or teratogenicity is identified in one of the two species. For pre- and postnatal development (PPND) studies, one species (rodents, rabbits, or NHPs) should be sufficient. However, the NHP is the least favorable species [6].

If the clinical candidate is only active in NHPs, the regulatory preference is to test the clinical candidate in the NHP, accepting the limitations of NHP studies and alternative approaches, including the use of surrogate molecules in rodent studies. If the sponsor chooses to use NHPs as the only relevant species, an enhanced PPND (ePPND) study [50] is typically initiated after the proof of conception with dosing continuing throughout gestation and into the postnatal period.

In general, the EFD toxicity studies should be conducted before enrolling a large number of women of childbearing potential in clinical trials (phase III) [6], and the PPND and ePPND studies should be available to support the submission of a marketing application. If NHPs represent the only pharmacologically relevant species, the ePPND study may be conducted earlier in development to support enrollment of women of childbearing potential rather than conducting a separate EFD study in NHPs.

*Juvenile Toxicity* The nonclinical safety information on the risk of direct exposure during postnatal development supports the use of biological products in pediatric populations. There is no specific regulatory guidance for nonclinical toxicity studies. However, the same approaches used with SMs should be used for the biological candidates. Overall, the need for a juvenile animal study is usually determined on a case-by-case basis, and the study should be conducted before initiation of clinical trials in pediatric populations.

***2.3.4.4 Genotoxicity*** Based on the ICH guideline S6 [5,7], standard genotoxicity assays, such as Ames assay, *in vitro* micronucleus, and *in vivo* micronucleus assays, are not required to be conducted for biological products because they would not be expected to interact directly with DNA or other chromosomal material [5]. However, for ADCs, although the complete ADC should not enter the nucleus to interact with DNA, the linker or linker and payload may; therefore, a genotoxicity assessment on the linker alone or linker and payload combination may be warranted.

***2.3.4.5 Carcinogenicity Studies*** As indicated in the ICH S6 guideline [5,7], standard carcinogenicity bioassays are generally inappropriate for biologics. However, assessment of carcinogenic potential may still be needed based on the duration of clinical dosing, patient population, or biological activity of the product (e.g.,

growth factors, immunosuppressive agents). In cases when the product is biologically active and nonimmunogenic in rodents, an assessment of carcinogenic potential may need to be evaluated in a single rodent species. When the product is not biologically active in rodents or results in a significant immunologic response, alternative approaches must be considered. These scientifically justified alternative approaches should be discussed with the regulatory agencies before conducting the work; this could include use of KO animals, *in vitro* cell proliferation assays, or standard 2-year carcinogenicity studies, and the use of a surrogate (although generally not favored) may be considered [55].

***2.3.4.6 Immunogenicity*** Almost all therapeutic proteins induce some level of an antibody response [36]. An immune response to a biologic in animals does not mean that it cannot be developed. Although such an antibody response does not necessarily cause severe side effects, clinical implications can occur. Antibody formation may lead to a loss of efficacy, neutralization of the endogenous counterpart, or general immune system effects (i.e., serum sickness–like disease, infusion reactions, anaphylaxis, and anaphylactoid reactions). In nonclinical studies, immunogenicity assessments are conducted to assist in the interpretation of the study results, although immunogenicity assessments from the nonclinical studies are not likely relevant for predicting the immunogenicity of human or humanized proteins.

Therefore, measurement of antibodies associated with administration of biological products should be performed when conducting repeated dose toxicity studies to aid in the interpretation of these studies. Antibody responses should be characterized (e.g., titer, number of responding animals, neutralizing or non-neutralizing), and their appearance should be correlated with any pharmacologic or toxicologic changes. Specifically, the effects of antibody formation on PK and PD parameters, incidence and severity of adverse effects, complement activation, and the emergence of new toxic effects should be considered when interpreting the data. Attention should also be paid to the evaluation of possible pathological changes related to immune complex formation and deposition. Humans may develop serum antibodies against humanized proteins, and frequently the therapeutic response persists in their presence. The nonclinical safety studies with biologics need to include an assessment of the immunogenicity of the protein. This is used to help to be able to interpret the results from the study [9,36].

***2.3.4.7 Tissue Cross-Reactivity*** There has been considerable discussion on use of the tissue cross-reactivity (TCR) study [56]. General consensus is that it should not be used as the basis to justify species selection for the toxicity program. TCR studies are used to provide an understanding of the biological distribution of the target in humans compared with relevant species used in the toxicology studies. For an ADC in which one is delivering a potent toxin to the cells, understanding the TCR may be critical to interpreting the results of the toxicology studies.

TCR studies should be conducted for therapeutic mAbs and related antibody-like biologics (defined as containing a complementarity-determining region [CDR]). The primary objective of the TCR study is to identify off-target binding and secondarily

to identify sites of on-target binding that have not been previously identified. A comparison of the patterns of staining between human and animal tissues may also be used to support the relevance of species evaluated in nonclinical toxicology studies but should not be used as the primary rationale for species selection; the selection of species for nonclinical toxicity testing should primarily be based on *in vitro* or *in vivo* pharmacology data (see Section 2.2). The results from the TCR studies are used to guide nonclinical and clinical investigators about potential target organs of toxicity based on the presence of staining in tissues.

A more detailed description of TCR studies, including a discussion of methodologies and interpretation, has been recently published [56].

***2.3.4.8 Cytokine Storm Assay*** There has been an awareness that administration of particular mAbs has been associated with a generalized increase in multiple cytokines (cytokine release syndrome) [57]. There is a heightened awareness that biologics that activate the innate immune system or that stimulate specific immune cells or malignant cells for immune-mediated destruction may be potential target for immune activation. Stimulation of these cells can result in a massive release of cytokines into the systemic circulation, such as what was seen as part of the cytokine storm that followed the administration of TGN1412. If the target of a biologic is likely to result in immune stimulation that could result in the release of cytokines, one needs to consider the potential for the cytokine release syndrome. The potential for this should be evaluated using human cells and cells from the appropriate animal species in which toxicity studies will be conducted.

## 2.4 PHARMACOKINETICS

The evaluation of the PK properties is important for biologics to allow for evaluation of the PK–PD relationship and to allow for data extrapolation from animals to humans. Although there are many similarities with what is required for an SM, there are some important differences, which are discussed in the following sections. Studies evaluating PK of vaccine candidates are generally not required [15,16].

### 2.4.1 Absorption

Most biologics generally have poor oral bioavailability, so administration is generally by the IV, IM, or SC route. Absorption of biologics after injection is influenced by the physicochemical properties and molecular weight of the protein, product excipients, blood flow at the injection site, temperature, and so on. Oral delivery is limited by barriers such as enzymatic and pH-dependent degradation in the gastrointestinal tract, and low membrane permeability. In general, oral bioavailability of biologics is erratic and less than 1% [58]. There have been several recent advances in increasing the absorption by nonparenteral routes of administration, but to date none have advanced into the market except a few through pulmonary delivery [59].

### 2.4.2 Distribution

Because of their large size, distribution of biologics is generally limited to the central compartment. Large proteins (molecular weight >30 kDa) cross blood capillaries slowly; however, they may bind to specific binding proteins involved in their transport and regulation, which may alter the distribution. In addition, there can be specialized mechanism for distribution into specific organs (e.g., CNS and fetus). The BBB is effective in preventing unregulated entry of substances from the blood, and it is equally effective at selectively permitting entry of necessary blood components. Extensive characterization of the transport of mAbs across the BBB has been started for potential utility in cancer therapy. Active transporters do exist for nutrients and regulatory molecules [60]. Of special relevance for antibody therapeutics, FcRn, the Fc receptor that protects antibodies from degradation in serum, is highly expressed in brain vessels [61]. In other organs, another function of FcRn is to transport antibody across tissue barriers. For the brain, a role in removal of harmful antibody from the brain has been suggested [62], but the actual roles are not yet known. In other tissues, FcRn-mediated transport is bidirectional, and the predominant direction can be modified experimentally [63]. The FcRn may also play a role in transporting mAbs across the BBB—or might be exploited for that purpose.

### 2.4.3 Metabolism

Biologics are generally degraded to smaller peptides or individual amino acids via pathways generally understood for the endogenous compounds. The individual metabolites (amino acids) would then be reused in the endogenous pool for the synthesis of structural and functional proteins. Because of the known metabolism to endogenous amino acids, metabolism studies generally required for new chemical entities are not needed for biologics.

The major site for the metabolism of biologics would be the same as for endogenous proteins, being the liver, kidney, the blood, and extravascular site of administration. The extravascular metabolism likely accounts for the low bioavailability observed after SC or IM administration compared with IV.

However, there are special instances when the metabolism of the biologic needs to be considered. ADCs, made of a mAb with an SM linker and payload, need to be evaluated for metabolism, release of the payload, and the PKs of the released product, including its metabolism and distribution. A more detailed understanding of the metabolism of the released substance may be accomplished through separate studies when the released substance is administered alone. However, these results cannot replace studies with the complete ADC because the distribution of the released product when administered alone may be different from that when released from the ADC.

### 2.4.4 Excretion

As outlined earlier, because biologics are generally degraded to individual amino acids and enter the endogenous pool, biologics are generally not excreted as unchanged proteins; therefore, evaluation of excretion is generally not required for a biologic, except ADCs where excretion of linker, payload, and metabolites, may need to be evaluated.

## 2.5 SELECTION OF THE INITIAL CLINICAL DOSE

Several good guidance documents outline the procedures for the selection of the initial starting dose for a human clinical trial [64,65]. Although these guidelines are generally focused on SMs, they may still apply to biologics. With respect to biologics, the criteria for setting the initial starting dose changed on March 13, 2006, when TGN1412, a mAb, was administered to humans for the first time, using initial starting doses consistent with the FDA guidance (i.e., using a fraction of the NOAEL dose level in nonclinical species). Severe, life-threatening toxicities ensued. The science behind these adverse events and the immediate responses to this event has been described in another article [29]. The incident with TGN1412 was a wake-up call to the pharmaceutical industry, the clinical trials community, and the regulatory agencies. The incident was investigated thoroughly by several different groups, including the Expert Group on Phase One Clinical Trials (chaired by Professor Gordon Duff) [66], the Royal Statistical Society, and the Early Stage Clinical Trial Task-force. Each of these groups issued reports that summarized the causes of the adverse events and proposed ways that such adverse events could be avoided in future FIH studies. This has led the European Union to issue "Guideline on Strategies to Identify and Mitigate Risks for First-in-Human Clinical Trials with Investigational Medicinal Products" [67]. The guideline is wide ranging in scope and is intended to assist sponsors in the transition from nonclinical to early clinical development. It identifies factors influencing risk for new investigational medicinal products and considers quality aspects, nonclinical and clinical testing strategies, and designs for FIH clinical trials.

Consistent with what we have discussed previously, the European Medicines Agency (EMA) guideline [67] describes the assessment of the relevance of the animal models and the need to ensure that the species used in the toxicology studies are pharmacologically relevant, with lesser emphasis on similarity of the metabolism of the clinical candidate in animals and humans (as has typically been the case for NCEs). The use of nonrelevant species in toxicology studies is strongly discouraged.

The guideline states that all available information has to be taken into consideration for the dose selection, and this has to be made on a case-by-case basis. In general, the NOAEL determined in nonclinical safety studies performed in the most sensitive and relevant animal species, adjusted with allometric factors or on the basis of PKs, gives the most important information. The relevant dose is then reduced or adjusted by appropriate safety factors according to the particular aspects of the molecule and the design of the clinical trials. However, for investigational medicinal products for which risk factors have been identified, the use of the NOAEL with appropriate adjustments may not be appropriate, and the use of the minimal anticipated biological effect level (MABEL) approach is recommended. The MABEL is the anticipated dose level leading to a minimal biological effect in humans. The guideline states that the calculation of MABEL should use all *in vitro* and *in vivo* information available from PK and PD data when such data may include (1) target binding and receptor occupancy studies *in vitro* in target cells from human and the relevant animal species, (2) concentration–response curves *in vitro* in target

cells from human and the relevant animal species and dose/exposure–response *in vivo* in the relevant animal species, and (3) exposures at pharmacologic doses in the relevant animal species [67].

When calculating the FIH dose using NOAEL data, safety factors should be applied to the calculation, and when using the MABEL approach, similar safety factors also need to be incorporated. However, the EMA guideline does not give insight as to the magnitude of the safety factor that should be used.

Although the EMA guideline describes two different (NOAEL and MABEL) approaches for the calculation of the FIH dose, the sponsor should look at the totality of the data available to them and evaluate several different approaches to the calculation of a safe starting dose and then take the most conservative approach. The calculation of the safe starting dose, as described in the EMA guideline, applies only to studies in normal healthy volunteers. The guideline acknowledges that "other approaches may also be considered in specific situations, e.g. for studies with conventional cytotoxic in oncology patients" [67].

## 2.6 FUTURE DIRECTIONS

To date the most common forms of biologics in development have been mAb, recombinant proteins, and vaccines. However, numerous new modalities are being developed. One of these new modalities is bispecific antibodies, which are able to recognize two distinct targets at the same time and might bridge two targets together, which present an opportunity for therapeutic gains (e.g., bringing cancer cells within closer proximity to cytotoxic T lymphocytes). When one considers species selection, if both CDRs do not have cross-reactivity to the same species, one needs to understand how to appropriately assess the safety if the full pharmacologic effect cannot be generated in one species.

As discussed throughout this chapter, ADCs are another new area for biologics that requires a unique approach for the nonclinical toxicity evaluation. There are currently two approved ADCs (Mylotarg® and ADCetris®), so the development path is a little more defined. However, the development of an ADC represents a hybrid approach between a traditional mAb and an SM.

A number of nucleic acid–based products are in development. These can generally be divided into gene therapy products, DNA vaccines, and antisense and RNA-based modalities. To date these nucleic acid–based products have not been approved for commercial use in humans, and therefore there is a less defined development path. However, some unique characteristics for each of these approaches need to be considered.

Gene therapy seems elegantly simple in its concept–supply the human body with a gene that can correct a biological malfunction that causes a disease. Researchers are testing several approaches to gene therapy, including replacing a mutated gene that causes disease with a healthy copy of the gene; inactivating, or "knocking out," a mutated gene that is functioning improperly; or introducing a new gene into the body to help fight a disease [68]. Some of the issues for the

nonclinical evaluation of gene therapy products deal specifically with the delivery system used and its acceptability in animal models. Additional issues are similar to those covered in previous sections: comparison of gene function in animals with humans, replacement of gene in normal animals, and relevance of a human gene in an animal. These all need to be considered when designing a toxicology program for a new gene therapy agent.

DNA vaccines represent another novel technology whereby genetic material (usually a plasmid) encoding an antigen is transferred to cells of a vaccine recipient. These cells express the antigen and present it to the recipient's immune system. The concern with DNA vaccines is slightly different from the concern for gene therapy because a DNA vaccine is not intended to be incorporated into the host DNA; therefore the concern revolves around incorporation of the plasmid DNA into the host chromosome DNA, resulting in long-term persistence and increasing the risk of mutagenesis and oncogenesis and the potential that the integration leads to vertical transmission [69,70]. This must be evaluated in a biodistribution study looking at the persistence and incorporation of the plasmid DNA into the host genome. An additional concern involves the potential for development of immune tolerance to the protein or the indication of autoimmunity through the induction of an anti-DNA immune response.

Antisense RNAs represent another new class of nucleic acid–based products that are currently in development. Antisense RNA acts by introducing a synthetic complementary (antisense) RNA (RNAi) into the cell. However, the uptake of RNAi has been somewhat slowed because of issues associated with delivery (how to target the RNAi to the cells of interest) and safety [71]. One also need to understand the sequence homology between the human RNAi and the animal species being used; if there is no match, then the consequence of the RNAi cannot be fully evaluated in the animal.

Stem cells represent a unique type of biologics; although not expressed by cells, they represent novel technologies. Several recent review papers describe some of the unique characteristics of stem cells that need to be considered in their development [72]. Of particular concern to stem cell products include the biodistribution (where do the cell go and how long do they last), immunogenicity (whether the cells are likely to be immunogenic and result in immune-based rejection), and tumorigenicity (whether the cells will differentiate into tumor cells and developing tumors, such as teratomas). Therefore, when developing a stem cell product, one needs to understand the distribution of the product after administration and the level of any residual undifferentiated cells and their ability to form a teratoma.

These new biologic modalities offer great promise for the treatment of diseases but also challenges in developing the nonclinical toxicology testing paradigm to ensure the safety of the patients in the clinical trials.

# Clinical Assessment of Biologic Agents

LESLEY ANN SAKETKOO, SHIKHA MITTOO, and LUIS R. ESPINOZA

## 3.1 INTRODUCTION

Biologic agents have become part of a powerful armament in the treatment of immune-mediated diseases, although long-term data are still being collected. It appears that biologics may have favorably altered outcomes in mortality and disability in recalcitrant and life-threatening diseases. At the same time, these "miraculous" agents come with important and potentially life-threatening concerns related to immune suppression that can give rise to serious infection, heart failure, demyelinating neural disease, and malignancy. Therefore, continued assessment of efficacy and adverse effects is central to the management of patients treated with biologics. This chapter outlines important considerations in the clinical assessment during and after a biologic clinical trial. This chapter covers structural aspects of clinical trial design and surveillance for adverse effects, provides an overview of endpoints in clinical trials design, and discusses the basis for generic (not disease-specific) and disease-specific instruments (i.e., outcome measures, endpoints) used in trials. This chapter also provides information on novel forms of developing clinical endpoints from the patient's perspective.

## 3.2 CLINICAL TRIAL STRUCTURE

### 3.2.1 Study Objective and Hypothesis Testing

Every investigation begins with a question in the mind of an investigator. This question is then transformed into a statement, according to scientific method, called a *hypothesis*. The hypothesis of the study is the foundation of the study design and drives the overall objective of the study. For example, an investigator may wonder if

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*,
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

drug A has better efficacy in controlling disease X than placebo; the hypothesis would be "drug A has better efficacy in controlling disease X than placebo." Here are some other examples: drug X has the same efficacy as drug Y but has less toxicity than drug Y, the test dose of drug X at 10 mg is more effective than 5 mg of drug X, and drug X at 10 mg is as safe as drug X at 5 mg. There is an unlimited number of hypotheses that exist or can exist. A study is designed with utility and efficiency in mind to gain data that will be useful on the performance of an intervention (in the case of biologics, administration of a drug). These data can then be tested against the hypothesis.

When there is a hypothesis, there is always a *null hypothesis*, which states the contrary to the hypothesis. The investigators set out to reject the null hypothesis. In our very first example, this would be "drug A does not have better efficacy in controlling disease X than placebo." Often, two types of hypotheses are tested when comparing one treatment arm with another–either that the two treatments have similar efficacy (*non-inferiority*) or that one treatment has a superior effect compared with the other treatment.

In addition to the hypothesis, other discoveries may be made during the course of the investigation. These discoveries may be unanticipated but important qualities of the drug, or there may be discoveries regarding the behavior of the disease in question; this is especially true if the disease is a rare disease. These findings may spark further investigations either within the same trial or in the context of a new investigation.

### 3.2.2 Standard Phases of Clinical Trials

Clinical trials involving medications that are seeking agency approval (e.g., US Food and Drug Administration [FDA], European Medicines Agency [EMA]) traditionally move through "phases." There are four phases; however, it typically requires passage of only the first three phases for the drug for application to the approval process. The phases of clinical trials investigate the study drug in a stepwise fashion. As the study drug's safety and efficacy are proven, each subsequent phase augments the number of research subjects to sequentially include more subjects with each phase.

*Phase I* is usually performed in a much smaller number of patients (~50 patients) than the other phases. It is designed to understand the pharmacokinetic effects in humans; to identify issues related to safety, toxicity (ability of patients to tolerate the drug), and side effects; and to understand a safe dosing range. A *phase II* clinical trial has a patient cohort that is larger, perhaps five to 10 times the number (~200) of a phase I trial. A phase II trial usually tests the efficacy of the study drug in different dosages to determine safe and efficacious doses for a particular disease or diseases. A *phase III* clinical trial is a confirmatory trial that attempts to verify the drug's safety and efficacy, which were demonstrated in the smaller trials, in a much larger group of patients (~1000 patients). A *phase IV* clinical trial is usually conducted to gain further understanding of the properties and performance qualities of the medicine in regard to dosing, risks, benefits, and so on. A phase IV trial is the only phase that is not necessary before agency approval of the study drug is sought.

### 3.2.3 Types of Studies

The gold standard of study design is the *prospective, double-blind, randomized, placebo-controlled clinical trial*. This has four components that are each considered the gold standard of each category:

1. The study collects data over the forward movement of time (rather than investigating data that were collected in the past). This is referred to as a *prospective* trial. Collecting data prospectively ensures that all expected points of data are able to be collected and in a uniform standardized method. This is the highest level of data collection. *Retrospective* data collection, whereby investigators attempt to answer a question or hypothesis by looking back in time, is fraught with many pitfalls because the data collection is rarely standardized at the points of collection and reporting. Data collected retrospectively are often culled from incomplete documentation. The sources of the data may be multiple or unknown reporters, rendering a proportion of the data difficult to interpret.
2. At all levels of the investigation, especially regarding the investigator and the patient, there is *blinding* (or *masking*) to whether the patient is receiving the study drug (or which dose of the study drug if multiple doses are used). A double-blinded study reduces bias from both parties that could potentially affect their responses in regard to endpoints and how they interact with each other. For example, if a physician is aware of whether or not a patient is receiving the study drug, the physician may unwittingly behave differently or speak in a different tone or phraseology that may have a positive or negative effect on the patient's response. It may also affect the physician's perspective of the patient's health and affect the results of data reporting, especially instruments such as the physician global score of disease activity. For many trials, complex efforts are undertaken to extend blinding to include the monitoring safety agency, recruitment personnel, and the statistician.
3. The patients are *randomized* to whether or not they will receive the study drug or what dose of the study drug will be received. Patients are randomly assigned without the cognizance of the investigating team assigned to one of the groups. This is often done via a computerized mechanism. Randomization reduces several levels of bias.
4. The study drug is compared with "no drug" in the form of a *placebo* that is delivered and looks exactly like the study drug. Humans have a tendency to respond to an intervention even when it is an "empty" intervention. Using a placebo group helps to control for the effect of this. A "no drug" placebo is often not ethical, as discussed later in this chapter.

Sometimes in rare diseases in which it is difficult to assemble a large cohort, for instance, it is not always feasible to perform a randomized, double-blind, placebo-controlled clinical trial. The following types of trials should be considered in contrast to the above "gold standard" components.

***3.2.3.1 Prospective Open-Label Observational Clinical Trial*** In this type of investigation, both the investigator and the patient are aware of the drug being administered. The data are collected over the forward movement of time, which allows for quality control of the data being collected, but both patient and investigator biases are introduced into the study, potentially affecting the results. It is commonly accepted that prospective open-label studies overestimate the efficacy of a study drug. This type of study, if the results are positive, may be the gateway to then conducting the much more expensive and labor-intensive randomized, double-blind, placebo-controlled clinical trial.

***3.2.3.2 Retrospective Analysis*** This type of study investigates how patients in the past responded to a drug. In this type of study, charts are reviewed. The data that were collected and documented by the treating physician at that point in time are often the only data available. There is often little uniformity of the data collected across patients. Often, there is much important data missing from the notes of the physicians in regard to confirmation of diagnosis, criteria that establish disease severity, and accurate documentation by the physician of quantifiable change of disease over time. In addition to challenges related to the physician's documentation, tests that would normally be obtained in a prospective study are often incomplete for any number of reasons (e.g., cost to patient, noncompliance of patient with testing, physician forgetting to order a test, lack of standardized reporting or interpretation of the test). It is very difficult to be certain of the quality of the data represented in these types of studies. Last, bias is inherent on many levels.

## 3.3 INCORPORATING PATIENTS INTO THE STRUCTURE OF A TRIAL

### 3.3.1 Treatment Groups and Cohort Enrichment

For a clinical trial, one must define the appropriate patients for inclusion. A group of patients to be studied is called a *cohort*. After diagnosis is confirmed by using strict and standard diagnostic criteria, it is important to identify patients with active disease who are likely to respond to an efficacious intervention; this is often referred to as *cohort enrichment*.

It is of great importance to understand that although a patient may have a diagnosis of a disease, the disease may not actually be active in that patient or not severe enough to warrant treatment. As an example, some autoimmune diseases may "burn out," and although the patient may have residual damage from a disease process that was once active (e.g., loss of the kidney's normal function in glomerular nephritis or stark abnormalities of the hands in rheumatoid arthritis [RA]), the disease is no longer progressive or active. Diseases also carry various rates of progression and severity of aggression. Sometimes a slow-moving disease may only warrant minimal intervention and observation.

For this reason, a minimal criterion of inclusion is established that defines the level of disease activity sufficient for inclusion in a particular clinical trial. A

minimal criterion for inclusion often targets patients with moderate to severe disease; however, some clinical trials are designed for patients with mild active disease. Patients may also be stratified by the severity of their disease into several groups within one clinical trial. Other stipulating descriptions of the cohort, depending on the hypothesis of the study, might be that patients are either naïve to treatment, have failed nonbiologic therapy, or perhaps have failed treatment on another biologic. (Treatment failure may be defined as either a lack of efficacy or patient intolerability to the treatment.)

An important component of a cohort that needs to be carefully defined before initiation of the clinical trial is a description of the exclusion criteria. Exclusion criteria are designed to exclude potential mimics of the target disease that would confound the results. Patients may also have other conditions or diseases in addition to the disease being studied. These are called *comorbid conditions*. It may be necessary to exclude patients with certain comorbid diseases such as renal failure, heart failure, lung disease, and so on. The natural progression of the patient's comorbid disease could potentially confound the interpretation of the safety results of the chosen clinical endpoints, or in certain instances, the study drug could potentially harm patients (e.g., in a patient with renal failure with a study drug that is known to rely on renal excretion). As a result of such stringent inclusion and exclusion criteria, inferences and conclusions from clinical trials are not likely representative of "real-world" clinic patients, patients who are more heterogeneous in their clinical disease activity and course. Often, phase IV trials provide further data in this arena.

### 3.3.2 Comparative Groups Within Clinical Trials

The most basic construct of comparison is the *treatment group versus control group*. To be able to quantify the efficacy and safety of an intervention, the performance of an intervention is compared against a *control group* that receives either a placebo or another medicine. Different treatment groups within a clinical trial are often referred to as *arms*, and frequently there are more than just two arms in a clinical trial (Fig. 3.1).

It is true that double-blind, randomized, placebo-controlled trials are the gold standard among the types of studies. However, it may not be ethical to use a placebo-only design in a comparative trial that could potentially result in harm, disability, or death to a patient who does not receive some form of efficacious treatment. In these cases, a number of modifications may be instituted with nonbiologic or other biologic therapy that is known to be efficacious in treating the disease in question. Additionally, if there is no promise of some potentially efficacious treatment (whether the new promising drug or the standard medicine), physicians are less likely to enroll very sick patients into a clinical trial. This concept would introduce a *selection bias* of patients who have less severe disease because physicians will not take the risk of losing a treatment opportunity in a patient with aggressive and progressive disease.

As mentioned earlier, there may be multiple "arms" within a clinical trial. The intervention group may have a number of comparative arms built into the trial design,

**FIGURE 3.1** An example of a cross-over study. In this example, the patient not meeting an endpoint over a specified period of time "crosses over" to the group with the medicine or with a higher dose of the study drug.

the most common being patients comparatively receiving different doses of the same medication. These groups may also be compared with an additional non-intervention group. Furthermore, clinical trials with multiple arms may provide the ability of the control or one of the comparative treatment arms to *cross over* if a clinical trial endpoint (see Fig. 3.1) has not been met within a specified period of time. A *cross-over design* builds into the design an opportunity for the research subject to receive the study drug or the study drug at a higher dose. Cross-over designs provide three important mechanisms to an investigation. First, cross-over studies allow patients with uncontrolled disease the opportunity to advance to a potentially more efficacious treatment if the assigned substance does not appear to be working. Second, cross-over designs provide an added dimension to the research, which allows for yet another opportunity to demonstrate potential superior efficacy with use of the study drug or with use of the study drug at a higher dose. Third, to continually allow patients in the less efficacious arms to cross over to the potentially more efficacious arm sequentially augments the final sample size of the potentially effective arm.

## 3.4 EFFICACY

### 3.4.1 Endpoints

Clinical trials are designed to meet clinical endpoints. Endpoints are a single measurement or combination of measurements that are thought to accurately reflect the current state of the activity of the disease compared with the same measurements obtained in the past or at future times. Endpoints must be able to reflect *sensitivity* and *accuracy to change over time*. For example, measuring joint deformity caused by

irreversible damage in RA is unlikely to show improvement of disease even if the disease has been effectively treated. However, swollen joints are a temporary state of inflammation; when the disease is controlled, joints are no longer swollen, or they may even worsen quantifiably if not treated. The number of swollen joints can be measured and compared over time. In this case, the endpoint is a physical examination finding, but it can be any parameter that is measured and reported at discrete points over time, such as laboratory values; scores on questionnaires; quantifiable changes on imaging; the decreasing dosage of another medication such as steroids; and even decreased number of events such as visits to the emergency department or hospital admissions, which are sometimes measured in asthma.

Qualities of a good endpoint are that it is *easy to interpret*, it *performs reliably* with repeated measurements, and it *directly measures what it is intended to measure*. Additionally, feasibility in regard to patient safety, cost, and availability of the test are important considerations [1–4].

Before detailing primary and secondary endpoints, it may be important to clarify what is a *surrogate marker*. A surrogate marker is a marker or endpoint that can be useful in measuring the activity of a particular disease because the marker is recognized to reflect disease activity; however, there is no guaranteed relationship that changes in the surrogate marker directly reflect disease activity. For example, serologic acute phase reactants, such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), are markers of inflammation and therefore rise in relation to inflammatory diseases such as RA and Crohn's disease. However, these markers may also be elevated in other situations such as infection. Ultimately, the change in levels of acute phase reactants is a peripheral phenomenon of the disease, not necessarily the action of the disease itself.

***3.4.1.1 Primary Endpoints*** The primary endpoint of a clinical trial is the defining measurement that the investigators agree on before the trial begins that will determine efficacy of the clinical trial. The primary endpoint is sometimes called the *primary outcome*. It is chosen because it is believed to be the single best reflection of disease activity for that particular disease in that particular clinical trial. As in RA, there may be a choice of several primary endpoints from which the investigators may choose. It may be a single measure or a combined response index that contains several measurements as part of a formula that provides a single result. An example of this is the ACR (American College of Rheumatology) 20 (see later discussion), which combines features of a physical examination, laboratory values, the patient's and the physician's overall perception of disease activity, and a score that reflects a patient's reported physical ability (may also be called *function*) (see later discussion for full details).

Additionally, a primary endpoint may be specified to be reached at a specified period of time within the duration of the clinical trial. For example, a trial may last for 1 year, but the primary endpoint is specified to be reached at week 26 with continued performance evaluation for the remainder of the year. Potential disease-specific primary endpoints are discussed for each disease below.

***3.4.1.2 Secondary Endpoints*** Secondary endpoints are important measures that are incorporated into a clinical trial to help investigators understand the intervention's impact on other areas of disease or the patient's life. These secondary endpoints may demonstrate the intervention's effect on parameters specifically related to the disease itself or to effects of the study medication on the patient. Secondary endpoints might be related to quality of life; assessment of fatigue, depression, or functioning; or the patient's or the physician's overall assessment of disease activity. Although we think of these endpoints as a secondary measure of disease activity, they can also be an indication of side effects from the study drug. For example, if patients in the treatment arm are showing worsening fatigue or mental health scores that are discordant with the trend of the primary endpoint, it could be a signal that these symptoms are related to the study drug itself.

An overview of generic (i.e., not disease-specific or validated across several different diseases) assessment tools most often used as secondary endpoints is provided in the following sections.

*Mental Health* Several instruments measure disease and medication effects on mental health. A few examples of the most commonly used instruments to measure depression and anxiety are described here.

The *Center for Epidemiology Studies—Depression Scale (CES-D)* is a 20-item questionnaire composed of short phrases that are scored on a scale of 0 to 3. The questionnaire asks about the patient's feelings and involvement in activities that might indicate depression.

The *Hospital Anxiety and Depression Scale (HADS)* is a 15-item questionnaire that has a depression component and an anxiety component that can be separated out if the investigator desires.

*Sleep* The *Medical Outcomes Study—Sleep Scale (MOS-SS)* is the most commonly used sleep scale. It is a 12-item questionnaire that asks about sleep disturbance, difficulty falling and staying asleep, feeling as though one has gotten enough sleep, and ability to stay awake during the day. It is important to remember that disease manifestations such as pain as well as medicines can affect sleep; prednisone is a good example.

*Pain* The Visual Analogue Scale (VAS) is the most commonly used method to assess pain (Fig. 3.2). It is often incorporated into other instruments such as the Health Assessment Questionnaire (HAQ).

*Physical Function* The HAQ and the HAQ-DI (Disability Index) are paper or sometimes electronic questionnaires given to the patient asking questions about physical ability and functioning in daily life as well as pain and the patient's perception of his or her health, both of which are done on a 15-mm VAS that the patient puts a mark through. A score is totaled at the end. To view the HAQ or the HAQ-DI, go to http://aramis.stanford.edu/HAQ.html. The HAQ and the HAQ-DI have also been adopted into other instruments such as the RAPID3 (see later discussion) [5,6].

**FIGURE 3.2** Visual analogue scale. The respondent, whether it is the physician or the patient, draws a line through the scale that corresponds to his or her perception.

*Health-Related Quality of Life* The SF-36 (Medical Outcomes Study, Short Form 36) measures health-related quality of life and has several components that measure disease impact on general health, pain, physical ability and function, mental health, energy, effect of work, and social activities. To view the SF-36, go to http://www.sf-36.org/tools/sf36.shtml.

*Worker Productivity* A field of secondary endpoints that has received much attention with great challenges in its measurement is worker productivity. Many diseases treated with biologics cause disability to the extent that work performance, productivity, presence, and imminent job loss (work instability) are affected [7–9]. One of the important goals of disease treatment is to have the patient return to as full a working life as possible. Developing and incorporating measurements that gauge disease effects on remunerative work are complex but are beginning to be introduced into the clinical trial setting [7–9].

***3.4.1.3 Obtaining Patient Perspective in the Development of Clinical Trial Endpoints*** Many of the instruments used in clinical trials for secondary endpoints are "patient-reported" endpoints; this means that the patient is asked to answer questions either as posed by the investigator, on a questionnaire (e.g., the SF-36, HAQ, or mental health scales), or on a VAS (e.g., for pain or perceived global health). These are very important; at one time, clinical trial data were limited to traditional "objective" measures of disease.

*Patient-Reported Outcomes* As discrete descriptors of domains, patient-reported measures are increasingly recognized as equal to or more important than traditional measures of disease activity [10,11]. For example, in patients with idiopathic pulmonary fibrosis, patient-reported dyspnea is recognized as an accurate and robust prognosticator of death [12]. To develop and select valid patient-reported outcome measures, disease experts need to consider incorporating the perspectives of patients because these perspectives supply crucial information. The reasoning behind obtaining the patient perspective supports that patients are a type of expert in the disease they are experiencing, and they see the disease from a different lens than that of medical experts. An example of this is fatigue in the clinical assessment of RA. Focus groups with

patients who have RA were conducted. It was through this forum whereby patients discussed what was important to them in relation to their disease that a new clinical endpoint was identified—fatigue. Fatigue was validated as an accurate and reliable reflection of disease activity that is sensitive to change over time [13]. Fatigue is now a mandatory endpoint in clinical trial design for RA.

Patients as consultants and advisors included early in the development and the process of clinical trials design and implementation is recommended by patient advocacy groups, investigators, and organizations such as OMERACT (Outcome Measures in Rheumatology), the World Health Organization (WHO), the US FDA, and the EMA [2–4,10,11,14]. We now realize there is much important information to be learned from the inclusion of patients' points of view.

## 3.5 PHARMACOVIGILANCE

*Pharmacovigilance* is the term that relates to scientific strategies to detect, assess, gain pathophysiological knowledge of, and ultimately prevent drug-related problems that arise in the postmarketing phase of a drug. Pharmacovigilance is driven by patient care and patient safety. It essentially includes monitoring for adverse outcomes, with the aim of ultimately providing clear information to health agencies and consumers developing risk–benefit profiles to aid in the most appropriate management decisions. Pharmacovigilance begins with surveillance that occurs at many levels, including the international (e.g., the WHO), national, and even institutional levels. Many countries have their own biologic registries and have been able to determine trends in certain types of malignancies, serious infections, and lung and heart involvement over short- and long-term periods after availability of a biologic.

### 3.5.1 Adverse Side Effects

There are many adverse side effects, which may be considered as follows: (1) common, but nuisance, side effects; (2) uncommon, but clinically relevant, side effects that include paradoxical adverse events; and (3) serious adverse effects. The three types of adverse effects from biologic clinical trial data are discussed in this section.

Before initiation of most treatment with biologics, whether for clinical trials or clinical practice, patients must be tested for tuberculosis (TB), hepatitis B, and hepatitis C. It is wise to get a history of recent travel as an indication of whether to screen further for the presence of latent infectious diseases [15].

Clinical trials for biologics usually monitor for changes in kidney function; liver function with alanine aminotransferase, aspartate aminotransferase, and bilirubin; lipid profile; and bone marrow suppression, which could be suggested by a decreased white blood cell count, anemia, and platelets. As a matter of course, electrocardiograms are often obtained periodically (or at least at baseline) to monitor for the development of cardiac conduction abnormalities (arrhythmias). Chest radiography is often obtained at baseline. The monitoring physical examination for adverse effects includes changes in weight, blood pressure, and cardiac

and pulmonary examination as well as examination for the development of edema and skin changes.

Common side effects are defined as effects that occur with a frequency of greater than 5% in the treated population. Symptoms experienced by patients are often nonspecific (e.g., gastrointestinal [GI] distress, headache), reversible, and self-limiting and are often experienced by both the treatment and placebo groups (if experienced by the placebo group, it is referred to as the *placebo effect*). Attributing an adverse effect to the experimental treatment requires statistically comparing the symptoms experienced by the treatment group with the those experienced by the placebo group. Examples of common side effects significantly associated with biologic therapies are injection site reactions and upper respiratory symptoms.

***3.5.1.1 Paradoxical Adverse Events*** Potentially unique effects of biologics are paradoxical adverse events. Biologic therapies for RA are designed to block upregulation or augmentation of select proteins that are involved in a complicated cascade of events leading to a particular outcome, such as joint inflammation. The proteins or cellular events that are antagonized often have multiple potentially opposing roles. In the case of tumor necrosis factor α (TNF-α), the role of protein may differ by tissue subtype or by stage of disease (in the case of cardiac failure) or may be expressed differently in different organ systems (e.g., there is less expression in skin). As a result of these variations and the fact that a variety of other relevant cytokine and protein networks are at play at any given moment, paradoxical adverse events may arise. As an example, TNF-α may promote or inhibit pulmonary fibrosis. By definition, TNF antagonism is suppression of inflammation and autoimmune consequences, yet it has also been the trigger of autoimmunity, being implicated in development of lupus-like reactions [16]. TNF inhibition in clinical trials has demonstrated efficacy in improving psoriasis, yet rare, paradoxical events of palmopustular psoriasis have been reported among treated patients [17].

***3.5.1.2 Serious Adverse Events*** The approval of the TNF inhibitor infliximab in August 1998 was preceded by only one case of TB being identified. The immediate months to follow saw a wave of TB cases reported to the FDA in striking temporal association with anti–TNF-α use with greater than 50% of patients presenting with disseminated and extrapulmonary disease involving lymph tissue, bone, bladder, bowel, and meninges [15]. After this devastating revelation, other serious infections also became apparent during the postmarketing period involving life-threatening bacterial, fungal, and parasitic infections. As an example, reactivation of JC (John Cunningham) virus is uniquely reported among patients who have received rituximab. Such surveillance and adverse outcome reporting are parts of an ongoing evaluation after a clinical trial demonstrates efficacy and safety and after agency approval. In the United States, all adverse events should be reported to the Adverse Events Reporting System of the FDA. Other countries maintain "biologic registries" that track many aspects of biologic use, including adverse events.

The importance of biologic registries across different ethnic populations cannot be underscored because certain ethnic populations may have predilections to

serious adverse events compared with other ethnicities. For example, the prevalence of methotrexate- and leflunomide-related pulmonary toxicity is reportedly higher among the Japanese registries compared with North American cohorts. Although it is recommended that clinical trials incorporate patients of diverse ethnic and social backgrounds, it is not always feasible. Moreover, because of the expense and logistics of conducting clinical trials, many trials are now being conducted in developing or select European communities where the socioeconomic fabric may differ significantly from the populations at risk. As a result, the inferences drawn from clinical trials may not necessarily be applicable to countries outside of those where the trials are conducted. Additionally, the location where a clinical trial is conducted may adversely impact ethnic health disparities and raise important ethical concerns. Although recruiting for marginalized ethnic groups has been a challenge in North American trials, this process provides the possibility to assess the outcome differences in various subgroups. The importance of clinical trials as it relates to ethnicity was highlighted in a landmark clinical trial of antihypertensive medication in African American patients. Angiotensin-converting enzyme inhibitors or angiotensin receptor blockade therapy was less effective in this ethnic group compared with whites. In the same vein, African American women with systemic lupus erythematosus are at increased risk for renal disease compared with whites, and North American Native American populations with RA are more likely to have higher disease activity and greater severity or burden of disease compared with whites with the same condition [18]. It is ethically important to be able to offer promising therapeutic options to patients who may have the greatest need but also to test the efficacy and impact of these therapies in these subgroups.

A continual surveillance for malignancy and serious infections is essential in the clinical assessment of biologic therapy. It is important to remember that although postmarketing surveillance is an important way to uncover harmful signals that may not be apparent in a shorter term clinical trial involving fewer patients or to uncover rare but clinically relevant adverse effects (e.g., TB), there is a potential reporting bias. This means that events should be interpreted cautiously, and one should also consider the lack of compliance with such monitoring systems, with events also potentially being underreported.

## 3.6 DISEASES TREATED WITH BIOLOGICS

Wide ranges of autoimmune inflammatory disorders are treated with biologics. In general, these autoimmune inflammatory disorders are characterized by perturbations in both innate and adaptive immune functions and probably are triggered by unknown exogenous or endogenous antigens. This section provides an overview of some of the diseases treated with biologic agents. This is not a comprehensive list, but it provides a background to help better understand the utility of endpoints in clinical trials for biologics.

### 3.6.1 Rheumatoid Arthritis

Rheumatoid arthritis is a disease of systemic inflammation that most obviously affects the joints with inflammation and destruction. However, RA can affect many organ systems, including the eyes, lungs, heart, and skin, with inflammation and vasculitis. Anti-TNF agents were the first widely used biologics in the treatment of RA. However, RA now has a number of FDA-approved biologics with different working mechanisms that include B-cell depletion with rituximab; interference of T-cell co-stimulation of cell interactions necessary for immune response with abatacept; and inhibition of interleukins IL-1 or IL-6 with anakinra and tocilizumab, respectively. Other biologics are in the pipeline and include small molecules such as syk kinase inhibitors JAK (Janus kinase) and STAT (signal transducer and activator of transcription).

Rheumatoid arthritis has been carefully studied for endpoints. However, no single component has been identified as being a pure reflection of disease activity in RA, although the following components are agreed to be important: the number of swollen joints, the number of tender joints, the duration of morning stiffness, the patient's report of global disease activity, pain, fatigue, progression of joint damage and erosions of bones as seen on radiographs, blood "surrogate" biomarkers reflective of inflammation such as ESR and CRP, physical function, and the broader evaluation of health-related quality of life.

The following are some of the disease-specific indices for RA commonly used as endpoints in clinical trials for RA.

In the ACR 20, ACR 50, and ACR 70, the number in the title corresponds to the percent of reduction in both tender and swollen joints and in at least three of five component parameters: pain by VAS, physician or patient global assessment of disease activity by VAS, function (by some accepted method such as HAQ), or the acute phase response (ESR or CRP). For example, an ACR 20 response would be a patient who at the beginning of the trial had 20 swollen joints, 25 tender joints, a pain scale score of 8, an HAQ score of 0.8, a physician global score of 6, and a patient global score of 8 with an ESR of 80 and after treatment was found to have a 20% improvement in the number of tender and swollen joints and improvement in at least three other parameters but no changes in physician global and HAQ. In this example, the patient has had large change in several areas, and although he or she has met the endpoint of ACR20, the HAQ and physician global scores have not changed much; however, this might be because the patient might have continued joint involvement in the hands, which would interfere greatly with functioning. This example illustrates the inherent challenges in these composite indices: although this patient has met this endpoint, many physicians would not consider that he or she has been treated satisfactorily.

The Disease Activity Score 28 (DAS28) is a composite endpoint; the 28 refers to the number of joints that are examined. This composite score is "weighted," which means that certain variables weigh more heavily than others. The formula is complex, involving mathematical applications such as square roots and logarithms to produce a score. In this case, the DAS28 gives more weight to the blood markers of inflammation (acute phase reactants) ESR and CRP. There is a concern that such

outcome measures are too reliant on this "surrogate" marker of disease activity, resulting in an overinterpretation of improvement [19].

Some disease activity composites do not include acute phase reactants. The Clinical Disease Activity Index (CDAI) is an unweighted calculation of the number of tender joints and swollen joints based on a count of 28 joints performed by the physician as well as patient global assessment and physician global assessment based on a 10-point scale distributed over a 150-mm line. The Simplified Disease Activity Index (SDAI) incorporates the same clinical measures as the CDAI but also includes the unweighted addition of the CRP level.

In contrast to the above activity scores, the Routine Assessment Patient Index Data (RAPID3) provides a fast (<10 seconds), feasible, informative quantitative index in patients with RA, and RAPID scores correlate significantly with the DAS28 and CDAI.

### 3.6.2 Osteoporosis and Malignant Bone Metastasis

Osteoporosis and malignant bone metastasis are diseases that are not directly immune mediated but are an indication for treatment with a biologic called denosumab, which is a monoclonal antibody against RANK ligand (receptor activator to nuclear factor κB). This ligand reduces the proliferation and activity of osteoclasts, which are central effectors of bone breakdown leading to osteopenia. RANK ligand may also have a role to play in RA, but at this time, there is no indication for treatment in RA. Endpoints to assess for efficacy in osteoporosis are changes in bone mineral density comparatively in the lumbar spine and the hip and a reduction in fractures of the treatment group compared with the control group. For metastasis, endpoints are a reduction in pain intensity, reduction in sites of pain, and reduction of new sites of bony metastasis as evaluated on imaging.

### 3.6.3 Inflammatory Bowel Disease

Inflammatory bowel disease (IBD), such as Crohn's disease and ulcerative colitis (UC), is an inflammatory and immune cell infiltration of the mucosa of the GI tract. The introduction of biologics seems to have decreased the need for surgical bowel removal and sequelae of IBD such as persistent bleeding, fistulas (nonhealing holes along the tract that allow fecal matter to communicate with areas of the body that should be protected from such). In UC, an immune-mediated inflammatory disease of the small bowel and colon, clinical trial endpoints are often a combination of the degree of bleeding, the frequency of stools, changes in the appearance of the mucosa on endoscopic examination, and the physician's global assessment of disease activity. These are most commonly assessed by the Mayo Score, which evaluates these properties on a 4-point scale that includes none or normal, mild, moderate, and severe.

Crohn's disease differs from UC in that it can occur anywhere along the GI tract from the mouth to the anus. Additionally, the immune-mediated effects may occur outside of the immune system involving the eyes, joints, and skin. The clinical trial

endpoint in Crohn's disease has consistently been the Crohn's Disease Activity Index (CDAI), which is a composite of items that are each weighted from a factor of 2 to 30 in a formula to ultimately produce a score. The components of the CDAI include the frequency of diarrhea, abdominal pain, the amount of antidiarrhea medications used, anemia caused by GI blood loss, and the existence of other manifestations thought to be related to the disease (e.g., arthritis, uveitis [inflammation of the eye], skin disease). These are then summed with a "weight factor" that takes into account the change in the patient's body weight, which should be improving if the disease is controlled and may be declining if the disease is active and the patient is unable to absorb the nutrients required to maintain a normal body weight.

### 3.6.4 Psoriasis and Psoriatic Arthritis

Psoriasis and psoriatic arthritis (PsA) are autoimmune-mediated diseases that can lead to joint destruction, disability, social isolation, and depression. In addition to skin lesions, PsA causes arthritis, dactylitis (sausage-like swelling of the digits caused by inflammation of the tendons running along the digit), inflammation, and fusing together of the spinal column and sacroiliac joints of the pelvis. Biologics have proved to have a high impact on recalcitrant disease.

Assessment of biologic agents in PsA include skin scoring and swollen and tender joint counts. The use of RA disease activity scales is acceptable and validated, but these scales do not perform optimally in individuals with PsA. Central to the assessment of PsA are skin assessment, peripheral joint assessment, patient global assessment, pain, physical function, and quality of life [20,21]. Other aspects that could be considered in clinical trial design are enthesitis (inflammation of tendon insertion to bone), dactylitis, spinal involvement, radiologic changes, physician global assessment of disease activity, and acute phase reactants.

Regarding skin involvement, a number of methods may be used to assess the degree of body surface area affected by skin disease.

### 3.6.5 Reactive Airway Disease

Asthma is a disease that is triggered by an outside or foreign antigen; the host's immune response overreacts to the antigenic presence. Omalizumab has been approved for moderate to severe persistent allergic asthma as demonstrated by serum immunoglobulin with a total IgE level greater than 30 IU/ml. Omalizumab is a monoclonal antibody that binds to free IgE, thereby preventing ensuing the binding of IgE (with bound allergen) to mast cells and basophils (important immune cells related to allergic reactions) and averting the allergic cascade that causes the bronchoconstriction of lungs resulting in an asthma attack.

Endpoints that have been specific to asthma in measuring efficacy of biologic agents are number of exacerbations, number of hospitalizations, ability to decrease use of inhaled steroids by 50%, and ability to discontinue use of an inhaled steroid. Other endpoints could include breathing tests both done by the patient and in the clinical setting.

## 3.7 FUTURE PERSPECTIVES

With the advent of newer and more powerful immunosuppressive and antiinflammatory drugs including the use of combination therapy, pharmacodynamics and pharmacokinetics are difficult to predict. Therefore, newer strategies including pharmacogenetics and biomarkers are being used to predict metabolic responses to a variety of immunosuppressive drugs to enable a more accurate prediction of their metabolic responses [22–24]. This, however, is an area of intense investigation, which will require large prospective trials with careful validation of data obtained.

# Key Regulatory Guidelines for the Development of Biologics in the United States and Europe[1]

RICHARD KINGHAM, GABRIELA KLASA, and KRISTA HESSLER CARVER[2]

## 4.1 INTRODUCTION

The United States and the European Union have distinct but overlapping schemes for the regulation of biologics, ranging from the definition of a biologic itself to the technical requirements for approval. In the United States, the definition of "biological product" was developed over time, and historical context continues to inform its interpretation. In the European Union, biologics are largely defined in terms of their active substances and methods of manufacture. Despite these differences, both jurisdictions recognize that biologics warrant special treatment because of their distinct characteristics, such as their complex structures and susceptibility to variation during manufacturing. Whereas in the United States, Congress enacted a separate statute for biologics, in the EU, the general approval scheme and certain specific requirements apply to biologics. Nevertheless, US and EU authorities have undertaken harmonization efforts with respect to some technical requirements for biologics applications; thus, there is significant overlap in requirements imposed by both regions. This chapter provides an overview of the US and EU regulatory schemes, from nonclinical trials through clinical trials to approval. It then discusses considerations for global development of biologics, and it ends by discussing special issues for developing vaccines.

[1] The chapter uses both the terms "drug" and "medicine" as they are used in the US and EU regulatory schemes, respectively.

## 4.2 GENERAL UNITED STATES REGULATORY SCHEME

### 4.2.1 The Definition of "Biological Product" and Its Significance

In the United States, "biological products" are subject to a different premarket pathway and differing intellectual property protections than products regulated only as "drugs."[3] Whereas a biological product must be licensed pursuant to a biologics license application (BLA) showing it is "safe, pure, and potent," the sponsor of a nonbiologic drug must submit a New Drug Application (NDA) showing the drug is safe and effective.[4] Certain new biological products receive 12 years of data protection, but new drugs receive up to 5 years of this protection.[5] Biologic and drug legislation also provide different schemes for resolving patent issues regarding entry of follow-on products.[6] Thus, determining whether a product meets the definition of "biological product" is enormously important.

Unfortunately, this inquiry is not straightforward. Drug and biologic legislation developed separately, and Congress did not provide detailed guidance for distinguishing biologics from other drugs. As a result, the Food and Drug Administration (FDA) and other agencies administering the biologics law over time have made these distinctions mostly on an *ad hoc* basis based on history and relevant precedents.[7] The FDA has recently proposed a bright-line rule for distinguishing "proteins" that qualify for treatment as biologics from certain other products that do not. This approach remains in the proposal stages, however, and history and precedent continue to play important roles in product jurisdiction determinations. This section outlines that relevant history.

In 1902, Congress passed the Biologics Control Act, which applied to "any virus, therapeutic serum, toxin, antitoxin, or analogous product applicable to the prevention and cure of diseases of man" and required licensure of facilities making these products.[8] Over the next hundred-plus years, Congress expanded this list of covered products to include, among other things, the following products and those "analogous" to them: vaccines, blood, blood products, allergenic products, and proteins (except chemically synthesized polypeptides).[9] Despite all of these

[3] Products meeting the "biological product" definition also meet either the definition of "drug" or "device" under the Federal Food, Drug, and Cosmetic Act (FDCA). Intercenter Agreement Between CDER and CBER (effective October 31, 1991) [hereinafter ICA], § II.

[4] Public Health Service Act (PHSA) § 351(a)(2)(C)(i)(I); FDCA § 505(b) & (d).

[8] Pub. L. No. 57-244, 32 Stat 728, 728 (1902). Congress added a product licensure requirement in 1944 and then replaced the dual license requirement with a single requirement for a BLA in 1997. Pub. L. No. 78-410, § 351, 58 Stat. 682, 702 (1944); Pub. L. No. 105-115, § 123(a), 111 Stat. 2296, 2323 (1997).

[9] Pub. L. No. 111-148, Title VII, Subtitle A, § 7002 (b)(2), 124 Stat. 119, 814 (2010); Pub. L. No. 105-115, § 123(d), 111 Stat. 2296, 2324 (1997); Pub. L. No. 91-515, § 291, 84 Stat. 1297, 1308 (1970); Pub. L. No. 78-410, 58 Stat. 682, 702 (1944).

amendments, Congress never defined the listed terms and, in particular, never defined "analogous," so the scope of the biological product definition remained unclear.

The overlapping definition of "drug" added to this complexity. The Food and Drugs Act of 1906 and the Federal Food, Drug, and Cosmetic Act of 1938 (FDCA) defined "drug" broadly to include, among other things, substances intended for use in the cure, mitigation, or prevention of disease, and the latter statute mandated submission of an NDA before marketing of a drug.[10] Although these "drug" definitions encompassed many biologics, the statutes did not provide concrete parameters for distinguishing nonbiological drugs from biological products. In 1944, when Congress revised and recodified the 1902 Act in the Public Health Service Act (PHSA), it clarified that the NDA requirement did not apply to biologics, but it did not elucidate the scope of the biological product definition.[11]

Regulators attempted to fill this gap by promulgating regulatory definitions of virus, therapeutic serum, toxin, antitoxin, and analogous product.[12] For example, the 1947 regulations, which are essentially similar to the current regulations,[13] defined products "analogous" to a toxin or antitoxin as those intended for preventing, treating, or curing diseases or injuries "through specific immunization."[14] The 1947 definition of products analogous to therapeutic serums excluded hormones.[15] Hormones such as insulin and human growth hormone were approved under the FDCA, not the PHSA.[16] Despite the 1947 regulations, differentiating biologics from drugs remained challenging at the margins.

[10] Pub. L. No. 59-384 § 6, 34 Stat 768 (1906); Pub. L. No. 75-717 §§ 201(g)(2), 52 Stat. 1040, 1041, 1052-53 (1938).

[11] See Pub. L. No. 78-410 § 351(g), 58 Stat. 682, 703 (1944) ("Nothing contained in this Act shall be construed as in any way affecting, modifying, repealing, or superseding the provisions of the [FDCA]"); H. R. Rep. No. 1364, 78th Cong., at 23 (1944) ("Subsection (g) is an explicit statement, confirming the present legal situation, that products subject to this section are not exempted from the [FDCA], except for the provision of that act relating to the licensing of new drugs").

[12] 42 C.F.R. § 73.1(g) (1949); see, e.g., Treasury Dep't, U.S. Pub. Health & Marine-Hospital Serv., Regulations for the Sale of Viruses, Serums, Toxins, and Analogous Products, Miscellaneous Publication No. 20, ¶ 16 (1909).

[13] 21 C.F.R. § 600.3(h) (2012). The FDA has not updated 21 C.F.R. § 600.3(h) to reflect that the statutory definition of biological product now includes products applicable to the prevention, treatment, or cure of "condition[s]" of human beings. For this reason, one court has concluded that the regulation is invalid "to the extent that [it] purports to eliminate the application... to 'conditions.'" *United States v. Livdahl*, 459 F. Supp. 2d. 1255, 1261 (S.D. Fla. 2005).

[14] 42 C.F.R. § 73.1(g)(5)(iii) (1949).

[15] *Id.* § 73.1(g)(5)(ii) (defining a product as analogous to a serum if it was "composed of whole blood or plasma or containing some organic constituent or product *other than a hormone* or an amino acid, derived from whole blood, plasma, or serum and intended for administration by a route other than ingestion") (emphasis added).

[16] Letter of Steven K. Galson, M.D., M.P.H., Director, CDER, to Kathleen M. Sanzo, Esq., Morgan, Lewis & Bockius LLP; Stephan E. Lawton, Esq., BIO; and Stephen J. Juelsgaard, Esq., Genentech, Docket No. 2004P-0231, PDN1 (May 30, 2006) (2006 Consolidated Response), at 44 & n.82; FDA, Ever Approved Drug Products Listed by Active Ingredient, at 2291 (printout dated August 2, 1989) (obtained via FOIA request) (listing NDA 1-754 for Sterling Drug Inc.'s insulin suspension product, approved November 27, 1939).

The advent of biotechnology, along with agency organizational disputes, brought this issue to the forefront of FDA's focus. In 1986, the FDA issued a policy statement stating that it would determine whether biotechnology products constituted biologics "based on the intended use of each product on a case-by-case basis."[17] Thus, the FDA continued to make product-specific determinations informed by history and precedent, and different units of the FDA had to agree on the approval pathway for a given product. This proved to be difficult, with press reports of "turf battles" between the Center for Drug Evaluation and Research (CDER) and the Center for Biologics Evaluation and Research (CBER) for jurisdiction over blockbuster biotechnology products[18] and claims that the decisions were "inconsisten[t]."[19] For example, epidermal growth factors were regulated as drugs because their first approved indications were traditionally drug indications.[20] Most monoclonal antibodies (mAbs) were licensed as biologics because of their biological source material and immunologic function.[21] Recombinant insulin and human growth hormone, similar to their naturally derived counterparts, were approved pursuant to NDAs.[22]

CDER and CBER subsequently executed an Intercenter Agreement (ICA) that attempted to clarify the governing authorities for products derived from living material. The agreement provided that the following products, among others, were subject to licensure under the PHSA: vaccines; proteins, peptides, and carbohydrates produced by cell culture (other than hormones and products previously derived from human or animal tissue and approved as drugs); proteins made in transgenic animals; blood and blood products; and allergenic products.[23] NDAs were required for, among other things, hormones (regardless of method of manufacture), synthetic mononucleotide and polynucleotide products, and naturally derived products other than vaccines or allergenics.[24] Twelve years later, the FDA consolidated review of most therapeutic proteins in CDER, but this transfer did not modify the governing statutory scheme for any ICA product, and the FDA continued to decide whether new products were biological products or nonbiologic drugs on a case-by-case basis using the principles of the ICA and historical precedent.[25]

In February 2012, the FDA issued draft guidance aimed at implementing recent legislation that added "protein (except any chemically synthesized polypeptide)" to the biological product definition.[26] In this draft guidance, the FDA proposed a

[26] Patient Protection and Affordable Care Act (PPACA), Pub. L. No. 111-148 § 7002(b)(2), 124 Stat 119, 814 (2010) (amending section 351(i) of the PHSA).

bright-line rule distinguishing proteins from "peptides" and "chemically synthesized polypeptide[s]" that the FDA proposes to approve under the FDCA.[27] The agency proposed to define "protein" as "any alpha amino acid polymer with a specific defined sequence that is greater than 40 amino acids in size."[28] According to the draft guidance, "peptides" have 40 or fewer amino acids and are not "proteins."[29] The agency also proposed to define "chemically synthesized polypeptide" as an alpha amino acid polymer that is made entirely by chemical synthesis and that has fewer than 100 amino acids.[30] Until the draft guidance is finalized, these definitions must be considered proposals. Nevertheless, they signal that the FDA might be shifting from its traditional, ad hoc approach to jurisdictional decisions to a new approach guided by bright-line rules.[31]

### 4.2.2 Nonclinical Studies for Biologics

Similar to other drugs, biologics must undergo laboratory and animal testing to define their pharmacologic and toxicologic effects before they can be studied in humans.[32] The legal framework for preclinical testing of biologics is essentially similar to that for drugs; for example, the FDA's good laboratory practice (GLP) regulations typically apply.[33] Nevertheless, biologics present special issues, necessitating a "flexible, case-by-case, science-based approach" to preclinical testing.[34]

For biotechnology-derived pharmaceuticals, the FDA has adopted the International Conference on Harmonization of Technical Requirements for the Registration of Pharmaceuticals for Human Use (ICH) S6 guidance, which describes the unique

[27] FDA, *Draft Guidance for Industry: Biosimilars: Questions and Answers Regarding Implementation of the Biologics Price Competition and Innovation Act of 2009* 13 (February 2012) (Q&A Draft Guidance). Sponsors of certain transitional proteins will remain eligible to submit their applications as NDAs during a transition period that ends on March 23, 2020. PPACA § 7002(e), 124 Stat. at 817. This option is available if a protein is the same "product class" as a biological product that was approved under the FDCA on or before March 23, 2010. Id. § 7002(e)(2). In the draft guidance, the FDA proposes to consider two products to be in the same product class if they "are homologous to the same gene-coded sequence," with allowances "for additional novel flanking sequences." Q&A Draft Guidance, at 14. Under the draft guidance, two products may be in the same product class even if their differences result in changes in pharmacokinetics, but not if the changes "alter[] a biological target or effect." *Id.* at 14–15.

[28] Q&A Draft Guidance, at 13.

[29] *Id.*

[30] *Id.*

[31] The FDA also has special rules for determining the regulatory status of tissue engineering and cell processing products. See 21 C.F.R. Parts 1270 & 1271. Detailed discussion of these rules is beyond the scope of this chapter.

[32] FDA, *Guidance for Industry: S6 Preclinical Safety Evaluation of Biotechnology-Derived Pharmaceuticals* 3 (July 1997) (S6 Guidance).

[33] 21 C.F.R. Part 58. For some studies using specialized test systems, it may be impossible to fully comply with GLP, but this might not preclude use of the studies to support clinical trial initiation and marketing authorization. S6 Guidance, at 3.

[34] S6 Guidance, at 1.

approach needed to selection of animal species and immunogenicity testing as overarching considerations and outlines typical preclinical testing.[35] Also, in May 2012, the FDA adopted the addendum to that ICH guidance.[36] Because Europe's Committee for Medicinal Products for Human Use (CHMP) approved that guidance nearly a year earlier, in July 2011, the addendum is discussed in Section 3.1, *infra*, but it is now equally applicable in the United States. Therefore, for a full understanding of nonclinical testing standards in the United States, readers should also review Section 3.1 of this chapter.

***4.2.2.1 Relevant Species*** Many biologics cannot be tested in commonly used animal species, such as rats and dogs, because of their biological activity and species- or tissue-specific activity.[37] Instead, sponsors must use a variety of tests, such as *in vitro* binding assays and functional tests, to identify a "relevant species," that is, "one in which the test material is pharmacologically active due to the expression of the receptor or an epitope (in the case of monoclonal antibodies)."[38] Generally, a sponsor should identify two relevant species, although one species may suffice when the product's biological activity is well understood or only one relevant species exists.[39]

In some cases, the chimpanzee—which cannot be sacrificed at the end of the study—is the only relevant species, and in other cases, identifying a relevant species might be impossible.[40] In these situations, the sponsor might need to consider alternative approaches to gathering animal data, such as the use of homologous proteins (which recognize the target protein or epitope in the animal),[41] transgenic animals that express the human receptor, or other animal models.[42]

***4.2.2.2 Immunogenicity*** Many biologics elicit immune responses, which can affect preclinical study results.[43] In some cases, these effects are desired (e.g., with a vaccine), but unwanted immunogenicity might be harmful. Potential undesired effects include neutralizing or prolonging the biologic's activity, forming immune complexes, or cross-reacting with endogenous substances.[44] As a result, sponsors

[35] *Id.* at 1 n.1. This guidance applies to biotechnology-derived proteins and peptides, their derivatives, and products of which they are components. It may also apply to recombinant DNA protein vaccines, chemically synthesized peptides, and plasma-derived products, among other things. It does not apply to allergenic extracts, cellular blood components, conventional bacterial or viral vaccines, DNA vaccines, or cellular and gene therapies. *Id.* at 2.

should obtain necessary samples for antibody testing during repeat-dose toxicity studies and, when interpreting the data, should consider the effects of antibody formation on pharmacokinetics (PK), pharmacodynamics (PD), and adverse events.[45] Detection of antibodies should not prompt termination of a preclinical study unless the immune response neutralizes the biologic's effects in "a large proportion" of the test animals.[46] Finally, sponsors should be aware that animals' immune responses are not indicative of those in humans.[47]

***4.2.2.3 Typical Preclinical Testing*** Sponsors usually must conduct PD studies, such as *in vitro* binding assays and *in vivo* studies that assess the product's pharmacologic activity and define its mechanism of action.[48] Biologics typically undergo single- and repeat-dose toxicity studies using relevant species, as noted earlier.[49] Safety pharmacology studies, which evaluate the product's functional effects on major body systems and specific organs, and local tolerance testing can be done separately or subsumed in toxicity testing.[50]

Sponsors also usually conduct single- and multiple-dose PK and/or toxicokinetic studies to assess absorption, disposition, exposure, and clearance (in particular, antibody-mediated clearance) and explore dose–response relationships.[51] This information is used to predict margins of safety for human studies. Immunogenicity testing might include screening and mechanistic studies, but animal models are not highly predictive of human immunogenicity.[52]

Typical carcinogenicity bioassays are "generally inappropriate" for biologics, although the S6 guidance calls for assessment of carcinogenicity when warranted based on the "duration of clinical dosing, patient population, and/or biological activity."[53] If concern exists regarding carcinogenic potential, the sponsor can consider several approaches to assess risk, including testing in a variety of malignant and normal human cells and further testing in relevant species.[54] According to ICH S6, reproductive and developmental toxicity studies may or may not be recommended, depending on "the product, clinical indication, and intended patient population."[55] Such studies using primate species pose challenges because of these animals' heterogeneous drug responses, high background abortion rate, and low number of offspring.[56]

Because biologics generally degrade into peptides and amino acids, classic biotransformation studies are unnecessary.[57] Genotoxicity studies also usually are not applicable to biotechnology-derived drugs because they are not expected to interact with DNA or chromosomes.[58]

### 4.2.3 Clinical Studies for Biologics

***4.2.3.1 The Investigational New Drug Application*** If a sponsor plans to perform clinical testing of a biologic in the United States, it must first have an investigational new drug application (IND) in effect.[59] An IND generally goes into effect 30 days after the FDA receives it.[60] During this 30-day time period, the FDA reviews the IND for any safety issues and may place a clinical hold on the study if, among other things, it presents an "unreasonable" risk to patients.[61] The IND must contain "[a]dequate" information from preclinical studies, on which the sponsor bases its conclusion that clinical trials are reasonably safe.[62] For well-characterized therapeutic biotechnology products, the IND should describe the product's pharmacologic effects and mechanism of action and provide information on its absorption, distribution, metabolism, and excretion.[63] Sponsors must include a description of the overall investigational plan and a protocol for each planned study; protocols not submitted in the initial IND should be submitted as protocol amendments.[64] The IND also must contain chemistry, manufacturing, and controls information sufficient to allow evaluation of safety.[65] This information is particularly important for many biologics, which may raise concerns because of their impurity profiles or the use of materials with unknown components in their manufacture.[66] The FDA recognizes that sponsors likely will change their manufacturing processes as development progresses. Section 2.3.4, infra, discusses the effects of these changes on product development.

***4.2.3.2 Good Clinical Practices*** Traditionally, the FDA used the phrase "good clinical practices" (GCP) to collectively describe a number of regulations and guidance documents with two overarching goals: (1) to ensure the integrity of data collected in clinical trials and (2) to protect clinical trial subjects.[67] In the mid

[66] Phase 1 Guidance, at 4–5. This Guidance applies only to well-characterized therapeutic biotech products. *Id.* at 2.
[67] *Good Clinical Practices (GCP)*, in BIOLOGICS DEVELOPMENT: A REGULATORY OVERVIEW 115, 115 (Mark Mathieu, ed., 3rd ed., 2004); see also 62 Fed. Reg. 25691, 25692 (May 9, 1997).

1990s, however, the ICH developed a consolidated GCP guideline, known as the E6 guidance, to harmonize standards for clinical study design, conduct, reporting, and recordkeeping.[68] The FDA has adopted this guidance. The agency recommends that sponsors use it when generating data for submission to the agency[69] and has stated that it will deem studies complying with ICH GCP as meeting the FDA's GCP standards.[70] This guidance supplements and clarifies FDA regulations on institutional review boards (IRBs) (21 C.F.R. Part 56), informed consent (Part 50), and clinical studies for drugs and biologics (Part 312). It describes the overarching principles for conducting clinical trials, the responsibilities of various parties involved with the clinical trial (IRB, sponsor, investigator), and the necessary documents for conducting a clinical study (e.g., the study protocol and investigator's brochure).[71] Sponsors should consider it in combination with the above-cited regulations, more recent FDA regulations (such as Part 54 on financial disclosures for clinical investigators), and more recently released FDA guidance on specific GCP topics.

***4.2.3.3 Study Design Considerations*** As with new drugs, clinical development of biologics typically involves three phases, which may or may not overlap. Biologics present several unique clinical considerations, however. Often, their clinical development programs must include an assessment of immunogenicity, which is typically not an issue for small molecule drugs. Also, because many biologics treat serious or life-threatening illnesses, their development may be compressed.[72]

Phase 1 studies involve the "initial introduction" of the biologic into a small number of humans to assess the product's metabolism, pharmacology, and safety at escalating doses.[73] Unlike phase 1 trials for nonbiologic drugs, phase 1 studies of biologics frequently involve administration to patients rather than healthy volunteers who will not derive benefit from them to ensure the risk–benefit profile of the product is acceptable for ethical purposes.[74] For example, studies may enroll patients when the biologic is known or suspected to be "unavoidably toxic," when there is a risk of antibody development to a native protein or mAb, or when the product's bioactivity is disease specific.[75] Phase 1 studies should determine the maximum tolerated dose and assess the product's bioactivity and PK to determine the optimum biological dose.[76] With respect to immunogenicity, these studies should assess subjects' antibody

[76] Matthews, *supra* note 72, at 81–82, 83.

development, both directly after administration and at least 28 days thereafter, and determine whether these results are linked to adverse events, PK, or PD.[77]

Phase 2 trials are controlled studies that evaluate short-term adverse events and effectiveness for a specific use in several hundred patients.[78] These studies further explore exposure–response relationships and the biologic's PK, PD, and immunogenicity, and they provide information to help refine the phase 3 protocol, including with respect to size, population, and endpoints.[79] Biologics sponsors often combine phase 2 studies with phase 1 or phase 3 studies.[80]

Phase 3 studies enroll patients and provide primary evidence for labeling claims and risk–benefit assessment.[81] They are larger than phase 2 studies, but their size ranges considerably depending on the patient population and the availability of alternative therapies.[82] They typically are randomized, double blinded, controlled, and performed at multiple study centers.[83] Placebo controls are used when ethical considerations permit, but in some cases (e.g., when effective treatment is already available and withholding treatment would expose subjects to unreasonable risks), active controls are used.[84] The studied patient population, as defined in the protocol's exclusion and inclusion criteria, should be representative of the population for which the sponsor seeks approval.[85]

Endpoint selection is critical to a successful phase 3 trial. The endpoint must demonstrate clinical benefit in the intended patient population.[86] Ideally, the endpoint is an established clinical outcome measure, although validated surrogate endpoints may be used in some cases.[87] If the endpoint is not well defined, the sponsor might have to combine use of several effectiveness outcomes.[88]

Several alternatives to traditional endpoints are available. Under the accelerated approval scheme, eligible sponsors may obtain approval based on either (1) a surrogate endpoint that is "reasonably likely to predict clinical benefit" or (2) a clinical endpoint that is measurable earlier than irreversible morbidity or mortality and that is "reasonably likely to predict an effect on irreversible morbidity or mortality or other clinical benefit."[89] The evidence supporting an endpoint's

[89] FDCA § 506(c)(1)(A). In July 2012, Congress amended the criteria for accelerated approval as part of the Food and Drug Administration Safety and Innovation Act (FDASIA). Pub. L. No. 112-144 §§ 901-902, 126 Stat. 993, 1082-1088 (2012). The amended statutory provisions are discussed here. The FDA has not yet updated its accelerated approval regulations to reflect these statutory changes. See 21 C.F.R. Part 601, Subpart E.

likelihood of predicting clinical benefit may include epidemiologic, pathophysiologic, therapeutic, pharmacologic, or other evidence developed using biomarkers or other scientific tools.[90] To be eligible for accelerated approval, a medicine must be intended for a serious or life-threatening disease or condition.[91] The FDA may require that the sponsor of an accelerated approval product conduct post-approval studies to "verify and describe the predicated effect on irreversible morbidity or mortality or other clinical benefit."[92]

Another alternative, the "animal rule," applies only to biologics that address serious or life-threatening conditions caused by "exposure to lethal or permanently disabling toxic biological, chemical, radiological, or nuclear substances" and for which human efficacy studies are unethical and infeasible.[93] Under the animal rule, a sponsor may obtain approval based on human safety data and adequate and well-controlled animal studies show the product is "reasonably likely to produce clinical benefit in humans" if, among other things, available data allow selection of an effective human dose.[94] Sponsors obtaining approval under the animal rule must commit to conduct postmarket clinical studies to confirm clinical benefit.[95]

***4.2.3.4 Manufacturing Process Changes During Development*** Sponsors often change the manufacturing process of biologics before approval (e.g., to scale up from pilot production to full-scale manufacturing, to improve manufacturing efficiency, or to change the production facility).[96] Biologics are much more sensitive to process changes than chemically synthesized drugs, and process changes have the potential to adversely affect a biological product. As a result, the FDA will determine whether the sponsor must conduct additional studies to support licensure of the postchange biological product. The FDA has issued guidance that describes this inquiry.[97]

According to this guidance, the FDA deems pre- and postchange products to be "comparable" when testing shows that "the manufacturing change does not affect safety, identity, purity, or potency."[98] The FDA may require that the sponsor perform some combination of analytical testing, *in vitro* and *in vivo* biological assays, animal

tests (PK, PD, and/or toxicity), and clinical testing (pharmacology, immunogenicity, safety, and/or efficacy studies) to make this showing.[99] In determining the type and amount of data necessary to support a specific change, the FDA will consider the extent of manufacturing changes, the stages of manufacturing at which they occur, the profile of the prechange product, the ease of characterizing the product, and the results of the necessary tests.[100] Data from in-process assays at the affected phase of manufacture can be particularly important to this determination.[101]

For example, the FDA might require human pharmacology tests to assess changes—such as those in product formulation—that could affect PK or PD. If the change results in differences in structure, bioactivity, or PK that "are meaningful with respect to potential impact on the product's safety, purity, or potency," the FDA generally requires additional clinical study of the product's safety, effectiveness, or both.[102] The same is true when "analytical and other preclinical testing is not sufficiently sensitive or broad enough to detect such meaningful differences."[103] In contrast, changes in filling site might only require comparative data as to final release specifications and stability.[104] Because the FDA has broad discretion in formulating the testing requirements for a comparability showing, the agency encourages sponsors to consult with it before implementing the proposed process change.[105] In any event, the sponsor must fully describe the change in the IND or BLA.[106]

***4.2.3.5 Meetings with the Food and Drug Administration Before and During the Clinical Trial Period*** Sponsor meetings with the FDA are often critical to successful, streamlined clinical development. They can help sponsors avoid conducting expensive clinical studies that the agency would ultimately reject. The FDA has promulgated regulations and issued guidance on FDA–sponsor meetings. Except when otherwise noted, agreements reached at these meetings do not bind the agency; the FDA's regulations provide that action on meetings does not constitute final agency action.[107]

Sponsors can obtain several types of pre-approval meetings with the FDA. 21 C.F.R. § 312.82 describes two types of such meetings. First, under this regulation, the sponsor can seek a pre-IND meeting to reach agreement with the FDA on the design of preclinical studies needed to commence human testing.[108] Although the regulation notes that these meetings are available to sponsors of therapies for life-threatening or

[108] 21 C.F.R. § 312.82(a).

severely debilitating illnesses,[109] other sponsors can also obtain them. For example, the FDA has indicated that pre-IND meetings can be useful in various challenging development scenarios (e.g., when the sponsor has identified a concerning safety signal).[110] Second, after phase 1 data are available for a therapy intended for life-threatening or severely debilitating illnesses, the sponsor may meet with the FDA to reach agreement on phase 2 study design, "with the goal that such testing will . . . provide sufficient data . . . to support a decision on its approvability for marketing."[111]

Sponsors also may request End of Phase 2 (EOP2) meetings and pre-BLA meetings.[112] At EOP2 meetings, the FDA aims to evaluate whether proceeding to phase 3 is safe, assess the protocols for phase 3, and determine whether any other information will be needed to approve the product.[113] The FDA will record any agreements reached in minutes and transmit them to the sponsor, and studies conducted in accordance with an agreement will be "presumed sufficient" for approval unless a "significant scientific development . . . requires otherwise."[114] Pre-BLA meetings are intended to identify "any major unresolved problems," discuss analysis of the data, and agree on the approach to formatting the BLA.[115]

The FDA classifies its meetings with sponsors into three categories. Type A meetings relate to "an otherwise stalled product development plan."[116] These include certain meetings to discuss clinical holds, meetings to resolve disputes with the FDA, and meetings to discuss the FDA's evaluation of Special Protocol Assessments (SPAs), described later.[117] Pre-IND, EOP1, EOP2, and pre-BLA meetings typically are Type B meetings.[118] All other meetings are Type C meetings.[119] Type A and Type C meetings have the shortest and longest time lead times to meeting dates, respectively.[120] FDA guidance and regulations describe the recommended content of the meeting request and pre-meeting briefing package, procedures for pre-meeting communication to narrow the topics for discussion (if possible), and the FDA's

practices for documenting the substance of the meeting in official meeting minutes and for resolving disputes concerning these minutes.[121]

Sponsors also may request an SPA and accompanying meeting. Pursuant to Section 505(b)(5) of the FDCA and FDA guidance, the FDA must grant "reasonable written request[s]" to meet with BLA sponsors to achieve agreement on the design and size of the following kinds of trials: (1) clinical trials intended to form the primary basis of an efficacy claim, (2) animal carcinogenicity protocols, and (3) final product stability protocols.[122] The agency must reduce to writing any agreements made through this SPA process and make them part of the administrative record.[123] The FDA cannot deviate from any such agreement unless the sponsor consents or the FDA identifies a significant scientific issue essential to determine the drug's safety or efficacy.[124]

### 4.2.4 The Biologics License Application

***4.2.4.1 Contents of the Biologics License Application*** Unlike the drug regulations, which specify the required contents of an NDA in great detail, the regulation on BLA content is quite brief. Under 21 C.F.R. § 601.2, the BLA must contain, among other things, nonclinical and clinical data showing the biologic's safety, purity, and potency; a "full description of manufacturing methods" for the product; stability data substantiating the expiration date; product samples and a summary of test results for the lot from which they derived; proposed labeling, enclosures, and containers; and the addresses of manufacturing facilities.[125] Although this regulation is far less prescriptive than its counterpart in the NDA regulations,[126] the FDA expects BLAs to contain essentially the same information and data as NDAs, and the electronic Common Technical Document (eCTD) format is the FDA's standard format for both.[127] The FDA's approach thus accords with Congress' 1997 directive that the agency "shall take measures to minimize differences in the review and approval of products required to have approved [BLAs and NDAs]."[128]

***4.2.4.2 Food and Drug Administration Review*** The Prescription Drug User Fee Act (PDUFA), which applies to most innovative biologics,[129] and the FDA's good

[129] FDCA § 735(1) (excluding whole blood, blood components for transfusion, allergenic extracts, and certain other biologics from the definition of "human drug application" for purposes of PDUFA).

review management principles and practices (GRMPs) govern agency review of BLAs.[130] Pursuant to PDUFA, the FDA levies "user fees" to defray part of its costs from reviewing applications and commits to performance goals for its review of those applications through a letter to Congress.[131] PDUFA sunsets every 5 years and was reauthorized for the fifth time in July 2012 (PDUFA V).[132]

After a sponsor submits a BLA, the agency assembles a review team comprising reviewers focusing on varying disciplines, such as clinical and toxicology issues.[133] The FDA then decides, within the first 60 days after submission, whether it can "file" the application (i.e., whether the BLA contains all information needed to permit a substantive review).[134] The FDA may issue a refuse-to-file decision if the BLA does not meet this threshold. During the filing period, the FDA will also decide whether to designate the BLA as a "priority" or "standard" application. For CBER-regulated applications, "priority" means that the biologic would constitute a significant improvement in the safety or effectiveness of treatment, diagnosis, or prevention of a serious or life-threatening disease.[135] In CDER, the same basic standard applies except that treatments for nonserious diseases also are eligible.[136]

In connection with PDUFA V, the FDA committed to "review and act on"—that is, issue an action letter for—90% of priority, original BLAs within 6 months of the 60-day filing date; the goal date for standard BLAs is 10 months from the 60-day filing date.[137] In the past, the FDA's actual performance has varied, with the agency meeting its PDUFA performance goals in some years but not others.[138] As part of its PDUFA V performance goals, the FDA committed to establish a new review model, known as "the Program," for original BLAs and certain NDAs. The Program offers

[137] PDUFA V Performance Goals, § I(E).

[138] Compare, e.g., FDA, *FY 2005 Performance Report to the President and Congress for the Prescription Drug User Fee Act* 11(indicating that, during fiscal year 2004, the FDA reviewed and acted on 97% of priority and standard applications within the specified time frames) with FDA, *FY 2009 Performance Report to the President and Congress for the Prescription Drug User Fee Act* 19 (indicating that, during fiscal year 2008, the FDA reviewed and acted on 85% of standard applications and 68% of priority applications within the specified time frames).

the opportunity for additional communication with the agency, including in a new "late-cycle" meeting.[139]

After FDA has begun substantive review of the BLA, reviewers may issue information request (IR) and discipline review (DR) letters to the applicant.[140] IR letters ask for specific information while review is in progress.[141] Reviewers issue DR letters at the end of a particular discipline review "to convey early thoughts on possible deficiencies." These letters do not necessarily reflect the input of their supervisors.[142] IR and DR letters do not stop the review clock.[143] Applicants may respond to IR and DR letters with additional information. This type of submission might constitute a "major amendment" to the application; if so, the FDA might extend the PDUFA goal date.[144]

Next, the FDA might seek an advisory committee's (AC's) advice on the application. By statute, the FDA must refer an original BLA to an AC or explain, in the action letter for the application, why that step was not taken.[145] The FDA typically requests that the AC address particular questions and vote on the answers, but the AC's advice does not bind the FDA.[146]

After the agency completes its review of the BLA, it will issue an approval letter, or a complete response letter (CRL), which states that the agency cannot approve the BLA in its current form.[147] A CRL lists identified deficiencies and, when possible, recommends sponsor actions to place the BLA in a position for approval.[148] An applicant may file a "resubmission" to address the deficiencies.[149] The review timeline for a resubmission depends on its content but is either 2 or 6 months from receipt.[150] An applicant also can request resolution of any dispute concerning the CRL.[151] If the FDA denies approval of the application, the applicant may request, and the Commissioner must issue, a notice of opportunity for hearing.[152]

***4.2.4.3 Approval Standard*** The FDA must approve a BLA if it shows that the proposed product is "safe, pure, and potent" and the facilities where the product

made, processed, packed, or held comply with good manufacturing practice (GMP).[153] Two FDA regulations define "safety" to mean "relative freedom from harmful effect" in light of the patient's underlying condition, assuming that the biologic is "prudently administered."[154] In determining whether this standard is met, the FDA must consider the risks of the product against its benefits.[155] Proof of safety comprises "adequate tests by methods reasonably applicable," including reports of "significant human experience" with the product.[156] "Purity" means that the finished product is "relative[ly] free[]" from "extraneous matter," including moisture and pyrogens.[157]

"Potency" means the product's "specific ability or capacity... to effect a given result" based on laboratory testing or controlled clinical data.[158] Thus, the FDA has interpreted "potency" to include effectiveness.[159] Nevertheless, the FDCA's requirement for "adequate and well-controlled trials," which typically means at least two pivotal clinical studies, does not apply to biologics in all circumstances.[160] Instead, this is a default requirement for biologics. Proof of efficacy must comprise adequate and well-controlled trials unless the sponsor shows that this requirement (1) "is not reasonably applicable" to the biologic or "essential to the validity" of the trial and (2) an alternative method is "adequate to substantiate effectiveness."[161] For example, serologic response evaluations may be sufficient when the correlation between the marker and clinical effectiveness has been established.[162]

## 4.3 EUROPEAN UNION GUIDELINES

In the European Union, biological medicinal product is an umbrella term covering a broad spectrum of medicinal products, all of which are larger and more complex than chemically synthesized products. Biological medicines are defined as "product[s], the active substance of which is a biological substance."[163] A "biological substance,"

[153] PHSA § 351(a)(2)(C); 21 C.F.R. § 601.3(a).
[154] 21 C.F.R. §§ 600.3(p), 601.25(d)(1).
[155] 21 C.F.R. § 601.25(d)(3).
[156] 21 C.F.R. § 601.25(d)(1).

[163] Section 3.2.1.1. Module 3, Part I, Annex I to Directive 2001/83/EC of the European Parliament and of the Council of 6 November 2001 on the Community code relating to medicinal products for human use (as amended by Directive 2009/120/EC of 14 September 2009).

in turn, is defined as "a substance that is produced by or extracted from a biological source and that needs for its characterization and the determination of its quality a combination of physico-chemical-biological testing, together with the production process and its control."[164] Annex II to the EU GMP guidelines notes that biologics "can be defined... largely by reference to their method of manufacture."[165] Examples of biological medicines include immunologic medicines; medicines derived from human blood and plasma; medicines developed by means of recombinant DNA technology, "controlled expression of genes coding for biologically active proteins in prokaryotes and eukaryotes including transformed mammalian cells,"[166] or hybridoma and mAb methods; and advanced therapy medicinal products.[167]

### 4.3.1 Nonclinical Studies

Similar to the FDA,[168] the CHMP has adopted ICH S6 as a guideline governing preclinical testing of biologics.[169] In July 2011, the CHMP adopted the addendum to this guideline, and the addendum came into effect in Europe in December 2011. The addendum complements, clarifies, and updates ICH S6 and is intended to further harmonize the standards for nonclinical studies. As explained in Section 2.2, we discuss the addendum here in light of the CHMP's earlier approval of it. The addendum and ICH S6 are applicable in both the United States and EU, however, and readers interested in understanding the nonclinical standards in either jurisdiction should review both sections.

***4.3.1.1 General Principles*** Although the addendum does not alter the scope of the ICH S6, it prevails whenever there are differences between the two.[170] The

[166] Section 1 of the Annex to Regulation 726/2004/EC of the European Parliament and of the Council of 31 March 2004 laying down Community procedures for the authorisation and supervision of medicinal products for human and veterinary use and establishing a European Medicines Agency (as amended by Regulation (EC) No. 1394/2007 of 13 November 2007).

[167] Section 3.2.1.1. Module 3, Part I, Annex I to Directive 2001/83/EC of the European Parliament and of the Council of 6 November 2001 on the Community code relating to medicinal products for human use (as amended by Directive 2009/120/EC of 14 September 2009).

[168] See *supra* Section 4.2.2.

[169] Guideline on pre-clinical safety evaluation of biotechnology-derived pharmaceuticals (ICH S6) (CPMP/ICH/302/95) (in operation from March 1998).

[170] See generally Addendum to Guideline on pre-clinical safety evaluation of biotechnology-derived pharmaceuticals (ICH S6), EMA/CHMP/ICH/731268/1998 (July 2011) (ICH S6 Addendum). Unlike ICH S6, the addendum advises that sponsors of nonclinical trials for biologics used in cancer treatment should consult the ICH S9 guideline. ICH S6 Addendum, at Section 1.3; Note for guidance on nonclinical evaluation for anticancer pharmaceuticals, EMEA/CHMP/ICH/646107/2008 (November 2009).

addendum covers the following five topics: species selection, study design, immunogenicity, reproductive and developmental toxicity, and carcinogenicity.[171]

***4.3.1.2 Species Selection*** The addendum discusses the factors that sponsors should consider in selecting relevant species for nonclinical testing.[172] According to the addendum, initial testing should compare target sequence homology between species, with subsequent *in vitro* assays making qualitative and quantitative cross-species comparisons of relative target binding affinities, receptor–ligand occupancy, and kinetics. Sponsors also should assess functional activity. This testing should permit identification of a species model that can demonstrate potentially adverse consequences of target modulation.

When the preceding approaches cannot be used to determine relevant species, the sponsor may conduct tissue cross-reactivity studies. If no relevant species exists, the sponsor may consider homologous molecules or transgenic models, as noted in ICH S6.[173] Specific instructions are provided for mAbs, for which a short-term safety study in one species—and no additional toxicity studies—are recommended.[174]

If there are two relevant species (one rodent and one nonrodent), the sponsor should conduct short-term studies in both. If the toxicologic findings from these studies are similar for both species, long-term studies may involve one of those species, usually the rodent species.[175]

***4.3.1.3 Study Design*** Sponsors should consider PK–PD approaches—such as exposure–response relationships, modeling, or simulation approaches—when selecting the high dose for toxicity testing. The high dose should be the higher of (1) the dose providing the maximum intended pharmacologic effect in the preclinical species and (2) the dose providing "an approximately 10-fold exposure multiple over the maximum exposure to be achieved in the clinic."[176] When no PD endpoint is available, the sponsor should select the high dose based on PK data, as well as available *in vitro* binding and/or pharmacology data. Generally, repeat-dose toxicity tests should have a duration of 6 months; studies of longer duration are not considered valuable.[177]

Finally, the sponsor may need to assess subject recovery from the medicine's pharmacologic and toxicologic effects when these effects occur at clinically relevant exposures. One approach is to include, in at least one study, a nondosing period assessing the reversibility of the toxic effects.[178]

[176] *Id.* at Section 3.1.
[177] *Id.* at Section 3.2.
[178] *Id.* at Section 3.3.

***4.3.1.4 Immunogenicity*** As noted in ICH S6, nonclinical studies are not useful in predicting potential immunogenicity of human or humanized proteins in humans.[179] The addendum provides more detail than ICH S6 regarding situations when the sponsor should measure antidrug antibodies (ADAs), namely when (1) there is evidence of altered PD activity, (2) there are unexpected changes in exposure in the absence of a PD marker, or (3) there is evidence of immune-mediated reactions. Collection of appropriate samples during the study is recommended, as noted in Section 2.2, because it is hard to predict the need for ADA measurement before the completion of the in-life phase of the study.[180]

***4.3.1.5 Reproductive and Developmental Toxicity*** The addendum first provides general advice on reproductive and developmental testing and then discusses more specific recommendations for fertility studies, embryo–fetal development (EFD) studies and pre- and postnatal development (PPND) studies, and the timing of studies in nonhuman primates (NHPs).[181]

The addendum first discusses appropriate species for testing.[182] Reproductive studies should occur in a relevant species, but no such studies are required for products directed at foreign targets, such as bacteria and viruses. If the product is pharmacologically active in both rodents and rabbits, EFD studies should occur in both species unless teratogenicity or embryo–fetal lethality is identified in one of them. Sponsors should not use NHPs in developmental testing unless they are the only relevant species, and even then, the sponsor can provide scientific justification to use an alternative model. If no relevant species exists, the sponsor may consider using transgenic mice or homologous proteins. If the weight of the evidence (e.g., information regarding the mechanism of action, phenotypic data from genetically modified animals, or class effects) suggests an adverse effect on fertility or pregnancy, this information may permit communication of the risks, and additional studies might not be warranted.

Fertility studies should occur in mice or rats when either is a relevant species. Mating studies are impractical for NHPs, but sponsors can evaluate the reproductive tract in repeat-dose toxicity studies of sexually mature NHPs that last at least 3 months.[183] Concerns about effects on conception or implantation should be addressed through studies of NHPs, a transgenic model, or a homologous protein or through risk management, informed consent, and labeling. With respect to EFD and PPDN, the sponsor may conduct separate studies or may consider one study that covers day 20 of gestation to birth (an enhanced PPDN or ePPND).[184]

[179] See *supra* note 47 and accompanying text.

[181] *Id.* at Section 5.
[182] *Id.* at Section 5.1.
[183] *Id.* at Section 5.2.
[184] *Id.* at Section 5.3.

If the candidate enters clinical trials before completion of EFD studies, appropriate risk management techniques (e.g., contraception) should be used in any clinical trial involving women of childbearing potential.[185] If these precautions are in place and NHPs are the only relevant species, the sponsor can conduct EFD and ePPND studies during phase III. When these precautions are not possible, the sponsor should submit the complete EFD report or interim ePPND study before beginning phase III.[186] When the product's mechanism of action raises serious developmental toxicity concerns and NHPs are the only relevant species, no study is necessary; instead, the labeling should disclose the concern, and the sponsor should avoid administering the candidate to women of childbearing potential.

***4.3.1.6 Carcinogenicity*** As noted, carcinogenicity assessments of biologics are not always warranted, but the addendum provides advice for use in situations when they are appropriate.[187] According to the addendum, the sponsor may design a strategy addressing potential carcinogenicity based on a weight of evidence approach, including a review of relevant information, such as literature; information on class effects, target biology, and mechanisms of action; *in vitro* data; clinical data; and data from chronic toxicity studies.[188] In some cases, this review will be sufficient to address the carcinogenic potential.[189]

In situations when the mechanism of action raises concerns and the weight of the evidence supports them, the hazard should be addressed through product labeling and risk management practices.[190] If the weight of the evidence regarding a mechanism-based concern is instead unclear, the sponsor can propose additional studies to address it.[191]

When insufficient information exists on product characteristics and mechanism of action, a more extensive assessment might be appropriate, including, for example, additional endpoints in toxicity studies.[192] If this assessment suggests a carcinogenicity concern, sponsors may propose additional studies or labeling to address the concern.[193] If this assessment instead suggests no carcinogenicity concern, additional nonclinical testing is not recommended.[194]

### 4.3.2 Clinical Studies in Compliance with the Clinical Trials Directive

After complying with the preclinical testing requirements, biologics also need to undergo clinical trials before a marketing authorization application (MAA) can be

submitted. The Clinical Trials Directive sets forth the general requirements for clinical trials of medicinal products, including biologics.[195] Because some general standards may not be relevant or appropriate for biologics, however, regulators must take a flexible approach to trials of these products. This section summarizes the requirements of the Clinical Trials Directive, noting special considerations for biologics when necessary.

***4.3.2.1 Clinical Trial Authorization*** The Clinical Trials Directive and European Commission guidance[196] describe the steps that a sponsor must take before commencing a clinical trial. According to these documents, a clinical trial may commence only if (1) the anticipated therapeutic and public health benefits outweigh any foreseeable risks and inconveniences to the subjects; (2) the trial subjects understand the objectives and risks of the trial and give informed, written consent to participate; (3) the trial safeguards the physical and mental integrity of the subjects; and (4) insurance covers the liability of the sponsor and investigator.

To comply with these requirements, the trial sponsor must take certain steps. In general, the sponsor must take responsibility for the following: trial conduct, appointment of an appropriate investigator, selection of the institution that will conduct the trial, quality control, data collection standards, protocol drafting, and creation of the investigator's brochure.[197] The sponsor then must apply for approval from both the ethics committee in the country where the trial will be conducted and competent authorities of the Member States. Written authorization may be required for all biologics trials and is required for trials involving medicines containing genetically modified organisms, medicines for gene therapy, and medicines for somatic cell therapy (including xenogenic cell therapy).[198] The opinion of the ethics committee should be issued within 60 days. A review period of 30 days can be added for medicines requiring written authorization noted earlier, and for xenogenic cell therapy, there are no time limits for authorization. This time frame can be extended by an additional 90 days (in addition to the original 90 days) if the ethics committee consults a national group or committee. The trial may begin only if (1) the ethics committee has issued a favorable opinion

[195] Directive 2001/20/EC of the European Parliament and of the Council of 4 April 2001 on the approximation of the laws, regulations and administrative provisions of the Member States relating to the implementation of good clinical practice in the conduct of clinical trials on medicinal products for human use (as amended by Regulation (EC) No. 596/2009 of 18 June 2009).

and (2) no competent authority has informed the applicant of grounds for non-acceptance.[199]

#### *4.3.2.2 Good Clinical Practices and Other Considerations for Clinical Trials*

Clinical trials of biologics must comply with GCP, as described in Directive 2005/28/EC on Good Clinical Practice[200] and the ICH E6 guideline, which the CHMP has adopted.[201] The directive and guideline describe general governing principles for clinical trials. The rights, safety, and well-being of trial subjects must prevail over the interests of science and society. Investigators must obtain freely given informed consent from every trial subject before each subject is enrolled. Clinical trial information must be handled, recorded, and stored with respect for relevant confidentiality and privacy rules. Trials must comply with the ethical principles of the World Medical Association's Declaration of Helsinki. Specific GCP guidelines apply to trials of advanced therapy medicinal products.[202] These guidelines regulate issues such as the donation, procurement, and testing of human tissues and cells; the implementation of a traceability system; and specific rules on safety reporting and long-term follow-up.

Under the Clinical Trials Directive, special requirements apply to clinical trials conducted on minors and other persons not able to give informed legal consent.[203] These requirements are intended to preserve the dignity of the trial subjects, confirm that the benefits of the trial outweigh the risks, and ensure that subjects' representatives give consent with as much involvement of the subject as possible. Competent authorities must record information regarding trials in the European database of clinical trials (EudraCT), which is accessible only to other competent authorities, the European Medicines Agency (EMA), and the European Commission.[204]

CHMP has issued a guideline on quality requirements during the clinical trial period for investigational medicinal products (IMPs) containing biological or biotechnology-derived substances.[205] The guideline describes quality documentation that should be submitted to the competent authority as part of the sponsor's investigational medicinal product dossier (IMPD). Given the importance of the production process for a biologic's properties, as described in Section 3, the

[204] *Id.* Article 11.

[205] Guideline on the requirements for quality documentation concerning biological investigational medicinal products in clinical trials, EMA/CHMP/BWP/534898/2008 (March 15, 2012).

guideline states that the IMPD should include, among other things (1) an adequate description of the process and process controls, including a flow chart of all successive steps and details of in-process testing, and (2) a description and justification of "any reprocessing during manufacture of the drug substance."[206]

The guideline also recognizes that sponsors will improve and optimize their manufacturing processes during clinical development and describes the steps sponsors should take following these changes.[207] Specifically, the sponsor must compare the quality attributes of the pre- and postchange biological active substances and relevant intermediates, and "[d]epending on the consequences of the change introduced and the stage of development, a comparability exercise may be necessary."[208] For first-in-human (FIH) clinical trials, sponsors should use product representative of the material used during the nonclinical testing phase.[209] Finally, with regard to characterization, the guideline requires details on the biological activity to be provided, recognizing that the extent of characterization data will further increase in later phases.[210]

***4.3.2.3 Study Design Considerations*** General guidance on study design applies to biologics as well as small molecule medicines.[211] According to the guidance, there is a "close, but variable correlation" between phase of development and type of study, but one type of trial can occur in several different phases.[212] The guidance therefore identifies the "[m]ost typical kind of study for each phase."[213]

Phase I usually involves the initial introduction of the investigational product into human subjects, and studies in this phase usually have nontherapeutic objectives. Specifically, phase I studies typically investigate one or more of the following: (1) initial safety and tolerability; (2) PK, which are "particularly important to assess the clearance of the drug and to anticipate possible accumulation of parent drug or metabolites and potential drug-drug interactions"; (3) PD; and (4) drug activity, to preliminarily determine the potential therapeutic benefit of a medicine.[214] The most typical phase I study is the human pharmacology study. According to the guidance, phase I studies may be conducted in healthy volunteers or certain types of patients (e.g., patients with mild hypertension). If the medicine has significant potential toxicity (e.g., cytotoxic products), the trial will usually be conducted in patients.

The CHMP introduced new guidelines on FIH studies after the 2006 TeGenero incident. That case involved a FIH clinical trial of a novel mAb, during which

[213] *Id.* at 3.1.3.1, 3.1.3.2, 3.1.3.3.
[214] *Id.* at 3.1.3.1.

subjects experienced severe adverse events, including multiorgan failure.[215] The new guideline describes risk factors helpful in identifying potential severe adverse reactions, including concerns derived from knowledge or lack thereof regarding (1) the product's mode of action, (2) the nature of the target, or (3) the relevance of animal models.[216] The guideline also discusses quality, nonclinical, and clinical study design considerations for minimizing risk to human subjects.[217]

The most typical phase II study is a therapeutic exploratory study that explores efficacy in narrowly defined, relatively homogenous groups of patients. Initially, studies may use a variety of designs (e.g., concurrent controls and comparisons with baseline status). Subsequent phase II trials usually are randomized and concurrently controlled, allowing for evaluation of the medicine's safety and efficacy for a particular indication. A major goal of this phase is to determine the dose(s) for phase III trials.[218]

Phase III typically involves therapeutic confirmatory studies that are designed to verify the preliminary evidence obtained in phase II and to provide a sufficient basis for marketing authorization. Phase III studies "may also further explore the dose-response relationship, or explore the drug's use in wider populations, in different stages of disease, or in combination with another [medicine]."[219] With regard to medicines administered for long periods, extended exposure trials ordinarily occur during phase III, although the sponsor may start them in phase II.[220]

To ensure that clinical trials in all three phases of development will be adequate to support an MAA, sponsors should design these trials with the MAA requirements in mind. Biologics in general need to comply with the requirements set out in Part III of the CTD, and advanced therapy medicinal products need to comply with the requirements described in Part IV of the CTD. Section 3.3, *infra*, provides more information regarding the MAA.

***4.3.2.4 Consultation with the European Medicines Agency*** A sponsor may obtain, from the EMA, scientific advice regarding clinical trial protocols.[221] Although this advice does not bind the ethics committee and national competent authority and is not binding for purposes of a future MAA, it can be useful to guide revisions to the protocol.[222] The agency's remarks will only address scientific issues

[222] EMA, Scientific Advice, http://www.ema.europa.eu/ema/index.jsp?curl=pages/regulation/general/general_content_000050.jsp&mid=WC0b01ac05800229bb&jsenabled=true (last accessed December 3, 2012).

and will generally focus on matters such as the selection of endpoints and comparator, the duration of treatment or follow-up, and the design of pivotal studies.[223] Advice also might address a sponsor's proposal to deviate from a CHMP guideline.[224] If the applicant decides not to follow the EMA's advice, it should justify this decision in its MAA.[225] EMA guidance details the procedures for requesting scientific advice.[226]

The fact that an applicant requests advice from EMA does not preclude it from also seeking advice from national competent authorities or from foreign regulators, such as the FDA. The process of obtaining advice from the national competent authorities is often less formal than requesting advice from the EMA, and such advice can prove helpful. Consequently, seeking such advice is a common choice among applicants.[227]

Applicants also may seek parallel scientific advice from the EMA and FDA.[228] Generally, the parallel scientific procedure is available for "important breakthrough drugs," products that the EMA and FDA have identified as falling within therapeutic areas of overlapping interest (e.g., oncology products, vaccines, and blood products), and products with "significant clinical safety, animal toxicology, or unique manufacturing concerns that could impede... development."[229] The goal of these meetings is to provide clarity regarding the regulatory requirements of each region and the reasons for any differences between them.[230] A sponsor requesting parallel advice should authorize the agencies to exchange all information about the product, including trade secrets.[231] After the parallel scientific advice procedure, each agency will provide its own independent advice on the questions at issue.[232] There is no guarantee of harmonized advice or identical regulatory decisions on the approvability of the product.[233] Nevertheless, sponsors are increasingly requesting parallel scientific advice. For example, in the period ranging from September 2009 to September 2010, the agencies received seven requests for such advice.[234]

### 4.3.3 The Marketing Authorization Application: Contents and Approval Standard

Many biologics fall under the scope of the centralized marketing authorization procedure, which is mandatory for medicines developed through biotechnological methods (recombinant DNA technology; controlled expression of genes coding for biologically active proteins in prokaryotes and eukaryotes, including transformed mammalian cells; and hybridoma and mAb methods).[235] For example, the following are subject to the centralized procedure: cell therapy, gene therapy, vaccines from strains developed through recombinant DNA technology (including gene deletion), and "any medicinal product for which a monoclonal antibody is used at any stage in the manufacturing process."[236]

Nonetheless, some biologics are still approved at the Member State level. For example, many vaccines do not fall within the scope of the centralized procedure. The EMA has published a guideline intended to harmonize the summaries of product characteristics and patient information leaflets for human vaccines.[237] This chapter discusses the requirements of the EU centralized procedure.

The approval standards for biotechnology products are the same as for chemically synthesized medicines. Both types of products must be safe and effective and have appropriate quality. Because of their special characteristics, however, biotechnology products must comply with several additional dossier requirements.

The MAA for a biotechnology product must meet the standard dossier submission requirements, as described in Article 8 of the Medicines Directive.[238] Consequently, the MAA must generally comply with the CTD format, including with respect to Module I (administrative information, including labeling and mock-ups), Module 2 (various summaries), Module 3 (chemical, pharmaceutical, and biological information), Module 4 (nonclinical reports), and Module 5 (clinical study reports).[239]

MAAs for biologics also must meet special requirements. The applicant must thoroughly describe the manufacturing process and must (1) provide information on the origin and history of the starting materials; (2) demonstrate that the active substance complies with specific measures for preventing the transmission of animal spongiform encephalopathies; (3) if cell banks are used, demonstrate that cell

[238] 8, Directive 2001/83/EC of the European Parliament and of the Council of 6 November 2001 on the Community code relating to medicinal products for human use (as amended by Directive 2011/62/EU of 8 June 2011).

[239] *Id.* at Annex I, Table of Contents.

characteristics remain unchanged at the passage level for production (and beyond); (4) provide information as to whether there are adventitious agents in seed materials, cell banks, pools of serum or plasma, and all other materials of biological origin, and, if it is not possible to avoid the presence of potentially pathogenic adventitious agents, show that further processing ensures elimination or inactivation of the agents; (5) if possible, base vaccine production on a seed lot system and established cell banks; (6) in case of medicines derived from human blood or plasma, describe the origin, criteria, and procedures for the collection, transportation, and storage of the starting material; and (7) describe the manufacturing facilities and equipment.[240]

Other special rules apply certain types of biological medicines. For example, for plasma-derived medicinal products, the applicant must provide an information dossier, the Plasma Master File. MAAs for vaccines other than for influenza need to contain a Vaccine Antigen Master File. Special rules also apply to advanced therapy medicinal products, including gene therapies, somatic cell therapies, and tissue-engineered products.[241]

## 4.4 REGULATORY STRATEGIES FOR WORLDWIDE MARKETING OF BIOLOGICAL PRODUCTS

### 4.4.1 Acceptance of Foreign Clinical Studies in the United States and Europe

***4.4.1.1 United States*** The FDA has adopted two regulations governing its acceptance of foreign clinical data, one applicable to supportive data and one applicable to data that form the sole basis for approval. Both regulations require the sponsor to meet certain conditions before the FDA will agree to use of the data.

First, the FDA accepts "well-designed and well-conducted" foreign, non-IND studies as "support" for an IND or BLA if two conditions are met.[242] The FDA generally must be able to conduct an onsite inspection of the data, if necessary.[243] The sponsor also must have conducted the study using GCP, as defined in 21 C.F.R. § 312.120.[244] For purposes of that regulation, GCP means standards that ensure the credibility of the results and the protection of subjects, including independent ethics board approval and documentation of subjects' informed consent.[245] Complying with ICH E6, the GCP guidance, is one way—but not the only way—to meet this requirement.[246] The FDA recently issued guidance on

[240] *Id.* at Annex I, Section 3.2.1.2.
[241] Advanced therapy medicinal products are regulated under a separate regime, Regulation 1394/2007/EC of the European Parliament and of the Council of 13 November 2007 on advanced therapy medicinal products and amending Directive 2001/83/EC and Regulation (EC) No. 726/2004 (as amended by Regulation (EU) No. 1235/2010 of 15 December 2010).
[242] 21 C.F.R. § 312.120(a)(1).
[243] 21 C.F.R. § 312.120(a)(1)(ii).
[244] 21 C.F.R. § 312.120(a)(1)(i).
[245] *Id.*; see also 73 Fed. Reg. 22800, 22807 (April 28, 2008).
[246] 73 Fed. Reg. at 22807.

submitting information to demonstrate compliance with 21 C.F.R. § 312.120.[247] After these threshold criteria are met, the FDA will use the factors described in ICH E5, *Ethnic Factors in the Acceptability of Foreign Clinical Data*, to determine the scientific relevance of the data with respect to the US population and the need for additional bridging data to confirm their value. This exercise is described in Section 4.2, *infra*.

Second, when foreign data are intended to form the sole basis for United States marketing approval, the sponsor must comply with GCP and meet three other criteria.[248] The FDA must deem the foreign data to be "[a]pplicable to the U.S. population and U.S. medical practice" using the criteria described in ICH E5.[249] The clinical investigators must have "recognized competence." Finally, the data must be considered valid without the need for an onsite FDA inspection, or the FDA must be able to validate the data through such an inspection.

***4.4.1.2 Europe*** Directive 2001/83/EC allows for clinical trials conducted outside the European Union to be taken into consideration during the review of an MAA in the European Union if such trials have been designed, implemented, and reported based on principles equivalent to those of the Clinical Trials Directive with regard to good clinical practice and ethical principles. Moreover, they should comply with the ethical principles outlined in the Declaration of Helsinki.[250] The applicant must submit a statement declaring such compliance as part of the MAA.[251]

In December 2008, the EMA published a strategy paper on the acceptance of data from foreign clinical trials conducted in "third countries," particularly those outside the "'traditional' Western European and North American research areas."[252] According to this strategy paper, there is a "growing concern both among regulators and in public debate about how well these trials are conducted from an ethical and scientific/organizational standpoint."[253] The EMA has called for increased cooperation between international regulatory authorities involved in the supervision of clinical trials and has put forth other proposals to address these issues.[254]

### 4.4.2 Foreign and Multinational Clinical Studies: Addressing Ethnic Factors

ICH E5 describes strategies to extrapolate clinical data generated in one region to support approval in another based on an assessment of ethnic factors' impact on the medicine's safety and efficacy.[255] "Ethnic factors" include intrinsic factors, such as genetics and age, and extrinsic factors, such as regional clinical trial conduct and medical practice.[256]

For the ICH E5 framework to apply, the clinical trial must meet the regulatory requirements (e.g., choice of control, trial endpoints, and key design features) of the region where approval is sought.[257] Regulators then assess the medicine's sensitivity to ethnic factors using information about its PK and PD and their relationship to safety and efficacy.[258] Based on the level of ethnic sensitivity, regulators will then determine whether existing data show the trials' relevance to the new region or whether a bridging study is necessary to confirm their relevance.[259] For example, when the medicine is ethnically insensitive and extrinsic factors in the two regions are similar, regulators might not require a bridging study.[260] Generally, one bridging study will suffice for extrapolation under ICH E5 unless the bridging study is too small to assess safety or does not confirm the relevance of the foreign data to the new region's population.[261] In these cases, regulators in the new region likely will require additional data. Depending on the circumstances, a bridging study might use pharmacologic endpoints or might constitute a controlled clinical trial.[262] Separate safety data might be needed when the sponsor does not need to perform a bridging efficacy study or when the efficacy study is not powered for safety.[263]

ICH E5 and its companion Q&A guidance also discuss strategies for a multinational trial to support simultaneous registration applications in multiple countries.[264] The trial's goals would be to show efficacy in each region and to compare regional results to show insensitivity to ethnic factors.[265] In designing these types of studies, sponsors should choose a primary endpoint that is acceptable to all regional regulatory authorities (or when this is impossible, collect data on all primary endpoints in all regions for comparison).[266] The sponsor should use a common

protocol to collect endpoint data and should power the study to permit an efficacy showing in each region.[267] Collection of safety data should be as uniform as possible across regions, and the study should meet all regional requirements for design and analysis.[268] Other factors relevant to study design, such as definition of disease and choice of control group, should be discussed with regional regulatory authorities.[269] The sponsor should provide the results by region and assess the consistency of the product's effect across regions.[270] When the regional results are persuasive, this showing can confirm the relevancy of the foreign results as further support for the regional marketing application.[271]

## 4.5 PREVENTIVE VACCINE DEVELOPMENT: SPECIAL CONSIDERATIONS

### 4.5.1 General Considerations for Vaccine Development in the United States

Development of a vaccine for FDA approval presents special issues. For example, vaccines are often intended for use in healthy populations; thus, they present distinct risk–benefit issues from therapeutic products.[272] As another example, data regarding concomitant use of other vaccinations are important to licensure.[273] Section 5.1 provides an overview of vaccine development issues in the United States, including necessary studies by phase of development, study endpoints, and the possible need for bridging studies.

***4.5.1.1 Types of Studies by Phase of Development*** For vaccines, phase 1 studies involve an initial assessment of safety and immunogenicity in a small number of healthy adult volunteers, ordinarily individuals at low risk of contracting the disease of interest.[274] The phase 1 study primarily assesses safety. Investigators should monitor patients for local and systemic adverse events at specified times in the week after administration and in the months that follow (including an assessment at 6 months after the last dose).[275] The protocol should include a toxicity grading scale for these events.[276] The stopping criteria generally must be more conservative than in therapeutic settings because vaccine trials enroll healthy individuals.[277] When the

sponsor studies a live vaccine, the phase 1 study should assess the "shedding" of live vaccine organisms in bodily substances, and investigators might need to isolate vaccinated individuals to evaluate shedding and any reversion of the vaccine strain to wild type.[278] The sponsor also might need to conduct additional studies assessing secondary transmission of the disease to third parties coming into contact with the vaccinated individual.[279]

Phase 2 studies should enroll individuals "at clear risk" for the disease.[280] These studies should produce "more definitive" immunogenicity data that allow the sponsor to determine whether an adjuvant is needed and to select the vaccine formulation, dose, dosing schedule, and route of administration for phase 3 trials.[281] Phase 2 studies also should evaluate the immune response to the vaccine upon administration with likely concomitant vaccines.[282] In addition to assessing the vaccine's effects, these studies also should assess the disease that it is intended to prevent, to allow refinement of one or more "case definitions" of the disease or infection to be prevented.[283] For example, the sponsor should gather epidemiologic data on the disease, including seroincidence data when applicable, in at-risk individuals and should determine geographic strain specificity.[284] By the end of phase 2, the sponsor should have developed and validated laboratory assays that will be used for the case definition for the efficacy trials (e.g., those used to distinguish wild-type immune responses from those that the vaccine elicits).[285]

Phase 3 studies should be controlled, randomized, and double blinded.[286] In formulating sample size calculations, sponsors should consider that multiple immunizations might be needed to achieve maximum efficacy.[287] When appropriate, however, sponsors may conduct a detailed safety assessment in only a subset of subjects as long as active monitoring for serious adverse events is in place for all subjects.[288] The FDA typically requires long-term follow-up, which might take the form of a postmarket commitment, to assess the duration of immunogenicity and efficacy, long-term safety, and the need for different doses.[289] "Ideally," the sponsor will evaluate the correlation of protection with immune response at specific time points after immunization as part of the phase 3 program.[290]

Sponsors should consider use of a Data Safety Monitoring Board (DSMB), which may conduct an interim review of the data, for the phase 3 vaccine trials.[291] The

protocol should specify the conditions that trigger any planned interim review, the statistical analysis plan for the interim analysis, and specific early termination criteria (e.g., criteria based on a toxicity grading scale).[292]

***4.5.1.2 Endpoints in Vaccine Studies*** The FDA accepts three types of endpoints for showing vaccine efficacy: (1) clinical endpoints (i.e., prevention of the disease in question); (2) immune response endpoints; and (3) pursuant to the animal rule described earlier in Section 2.3.3, animal study endpoints that are "clearly related" to the desired benefit in humans, such as survival or prevention of major morbidity.[293] First, the FDA generally mandates use of a clinical endpoint for vaccines that are novel or the first of their kind for the population, among other things.[294] Second, as noted earlier, the FDA will accept a serologic endpoint "where a previously accepted correlation between [this endpoint] and clinical effectiveness already exists"[295] (e.g., based on prior successful clinical studies using clinical endpoints or population-based studies of immunized individuals).[296] Because serologic endpoints may allow for smaller efficacy trials, however, their use in pivotal efficacy studies might result in a need for additional safety studies.[297] Third, sponsors can use the animal rule only when studies using clinical or serologic endpoints are unethical or infeasible; this might be the case for vaccines to address smallpox or anthrax, for example.[298]

***4.5.1.3 Necessary Bridging Studies*** Bridging data might be needed in several circumstances. For example, these data might be needed when the sponsor conducts efficacy studies abroad. In this case, the frameworks described in Sections 4.1.1 and 4.2 will govern the acceptability of the foreign data and the type of bridging studies needed to assess ethnic factors, respectively.[299] For vaccines studied in foreign efficacy trials, the FDA typically requires bridging data regarding safety and immunogenicity.[300] Similarly, when the manufacturer implements process changes after the pivotal study for a vaccine, the FDA may require clinical bridging studies between the pre- and postchange vaccines to assess whether the immune responses to both are equivalent and to evaluate safety.[301] If no immune correlate of protection has been identified and the new product elicits a decreased immune response, a comparability showing might not be possible.[302]

### 4.5.2 Special Procedures for Centralized Review of Vaccine Dossiers in the European Union

Under EU law, a fast track authorization procedure is available for pandemic influenza vaccines. The sponsor may submit, and obtain approval of, the core pandemic dossier during the interpandemic period[303] based on a "mock-up" vaccine (i.e., a vaccine containing an active ingredient that mimics the novelty of a pandemic virus).[304] After a pandemic is declared, the special procedure allows for fast track approval of a pandemic variation.[305] The manufacturers of influenza vaccines may submit the core pandemic dossier and the subsequent pandemic variation either to the EMA for a centralized approval or to the national authorities for a national or mutual recognition procedure approval.[306] The centralized procedure is obligatory for certain techniques of vaccine preparation, such as reverse genetics.[307]

### 4.5.3 Development of Vaccines to Protect Against Global Infectious Diseases

***4.5.3.1 United States*** The FDA reviews and approves vaccines for infectious diseases that are not endemic or have not been reported to occur in the United States, such as cholera, malaria, and tuberculosis.[308] The regulatory pathway, approval standard, and required level of evidence are no different for these vaccines and those intended to prevent diseases endemic in the United States.[309] For example, review under the animal rule is available under the same conditions for both types of vaccines.[310] The FDA has licensed several vaccines, including ones for Japanese encephalitis and typhoid, based on efficacy trials performed solely in disease-endemic regions.[311]

Because foreign efficacy trials likely will be necessary when the disease has a low incidence in the United States, the FDA's regulations governing acceptability of foreign data and ICH guidance on ethnic factors again are likely to apply.[312] In these situations, the "bridge" might comprise data from a single-arm safety and

immunogenicity study in the United States, from which comparisons can be drawn to pivotal foreign data.[313] Sponsors should discuss with FDA their plans for development of global infectious disease vaccines, including bridging study design and special issues for concomitant vaccines in this context.[314]

***4.5.3.2 Europe*** The CHMP may "give a scientific opinion, in the context of cooperation with the World Health Organization" regarding medicines that are intended exclusively for markets outside the Community and "used to prevent or treat diseases of major public health interest."[315] Eligible medicines include vaccines used in the World Health Organization Expanded Program on Immunization or vaccines for protection against a public health priority disease.[316]

## 4.6 CONCLUSION

Despite clear differences in the US and EU regulatory regimes for biologics—for example, with respect to the definitional frameworks for biologics—the systems share a number of similarities. Both regimes use certain harmonized scientific testing standards, and one can safely conclude that both regimes clearly recognize the specific nature of biologics and take appropriate measures to address the possible issues resulting from it. The regions have distinct regulatory approval procedures because of the general structural differences in their medicine authorization regimes, as well as different historical developments in both systems. Overall, the US and EU regulatory regimes for biologics are more similar than they are different.

# Landscape and Consideration of Intellectual Property for Development of Biosimilars

SRIKUMARAN MELETHIL

Prediction is very difficult, especially if it's about the future.

—*Niels Bohr*

## 5.1 INTRODUCTION

Biological products,[1] compared with drugs, are complex molecules such as proteins, hormones, vaccines, enzymes, and monoclonal antibodies (mAbs). Because of their general instability in the gastrointestinal tract, such products are generally administered by non-oral routes (e.g., intravenous, intramuscular). A visual representation of the magnitude of differences between drugs and biologics is depicted in a recent publication showing structural representations of a complex mAb and the small molecule drug aspirin.[2] Biologicals are often quite expensive. For example, the annual cost of Cerezyme used in the treatment of Gaucher disease is $200,000.[3]

[1] The term "biological product" means a virus, therapeutic serum, toxin, antitoxin, vaccine, blood, blood component or derivative, allergenic product, protein (except any chemically synthesized polypeptide) or analogous product, or arsphenamine or derivative of arsphenamine (or any other trivalent organic arsenic compound), applicable to the prevention, treatment, or cure of a disease or condition of human beings (42 U.S.C. § 262(i)(1)).

Patents on biological products with an estimated $10 billion in sales expired in 2010; this number is expected to double by 2015.[4] Therefore, cheaper versions of biological products are possible, at least in theory, and meet an important societal need.[5]

Biological products, with a few exceptions, are approved under § 351 of the Public Health Service Act,[6] which did not previously provide for the marketing of generic versions of such products until amended in 2010. Clearly, the approval of biosimilars in Europe starting in 2006 put considerable political pressure on the US Congress to act.[7] These amendments[8] can be found in the Biologics Price Competition and Innovation Act of 2009 (BPCI Act), which allows for the approval of generic biological products, also called follow-on biologics and biosimilars (this latter term will be used in this chapter). It is superficially modeled after the Drug Price Competition and Patent Term Restoration Act of 1984[9] (commonly referred to as the Hatch-Waxman Act), which provided a similar pathway for the entry of generic drugs, which are mostly composed of relatively smaller and simpler molecules.

Given the complex nature of biological products, many legitimate scientific issues regarding the safety and efficacy of biosimilars have been raised.[10] For example, minor lot-to-lot variations in manufacturing processes can lead to structural variability (e.g., extent of protein glycosylation), and the current limitations in analytical methodology may fail to detect these minor differences; such differences can affect the efficacy and safety (e.g., immunogenicity) of a biological product. Therefore, the challenges for a company to market a generic version of a biological product that is biosimilar to or interchangeable[11] with an existing biological product is considerably greater than with small molecule drugs. These scientific challenges are discussed in elaborate detail in other chapters in this book. A glimpse of these challenges of providing cost-effective biologicals to American consumers can be found in the following hopeful statement regarding the BPCI Act: "It is the sense of the Senate that a biosimilars pathway balancing innovation and consumer interests should be established."[12] Interestingly, independent analyses of cost savings to the federal

[11] Legal definitions for "biosimilar" and "interchangeable" are provided later in this chapter.

[12] Sense of the Senate (Patient Protection and Affordable Care Act, Pub. Law No.111-148, 124 Stat. 252, Title VII 7001(b).

government over a 10-year period have come up with estimates ranging from no (zero) savings up to $14 billion.[13] A 2009 Federal Trade Commission Report was not optimistic about the cost savings with the market introduction of biosimilars as compared with that of generic drugs.[14] Given the high cost of generating the required data to meet regulatory standards for biosimilars, it is likely that the market competition will "resemble brand-to-brand competition than the dynamics of brand-name competition under Hatch-Waxman."[15] In other words, cost differences between generic and innovator biologicals will not be as high as the comparable differences with nonbiologic drugs. The final answer to this question is likely to emerge when the savings are reported, as required by law.[16]

The purpose of this chapter is to introduce readers to the recently passed BPCI Act with special emphasis on the intellectual property (IP) provisions of the law, especially as they relate to patents and trade secrets. It begins with a brief legislative history to provide readers with an overview of the scientific, legal, economic, and political debate before the passage of BPCI Act. It is followed by a brief presentation of approval guidelines for biosimilarity to enable readers to obtain a better understanding of the scientific challenges associated with manufacturing biosimilars. Next, key IP provisions under the BPCI Act for innovator and generic manufacturers are presented. This is followed by certain legal issues that have been raised, such as challenges to the Food and Drug Administration's (FDA's) use of innovator data and postapproval applicability of safe harbor provisions. The chapter concludes with a future perspective that draws the attention of readers to certain widely debated IP and regulatory issues that will soon be or can be expected to be decided by the FDA and the Supreme Court. These decisions will likely have a major impact on the IP landscape and dialogue for biosimilars. Because scientists and other nonlawyers are expected to be a significant part of the reading audience, it is written with an explanatory tone to facilitate a better understanding of legal issues by these groups.

## 5.2 LEGISLATIVE HISTORY

A key point to be made is the diametrically opposite views of the two competing stakeholders—namely, the innovator and generic industries—over biosimilar approval. Although this can be expected, total disagreement over scientific issues, where there can be room for more agreement, may come as a surprise. For example, the effect of the manufacturing process on protein structure and function is a central

[13] Johnson, 2010.

[14] Federal Trade Commission. Emerging Health Issue: Follow-on Biologic Drug Competition, Washington, DC, June 10, 2009. Available from: http://www.ftc.gov/os/2009/06/P083901biologicsreport.pdf (henceforth, FTC 2009 Report).

[15] FTC 2009 Report, at p. iii.

[16] "The Secretary of the Treasury, in consultation with the Secretary of Health and Human Services, shall for each fiscal year determine the amount of savings to the Federal Government as a result of the enactment of [the BPCI Act]." question when it comes to biosimilars, which, as noted, are mostly complex molecules. During the preapproval debate over the BPCI Act, generic companies held the view that "[s]pecific aspects and parts of the manufacturing process do not determine the characteristics of a protein product"[17] because the "FDA had allowed innovator companies to make changes in manufacture, without subsequent clinical testing of the altered product."[18] In contrast, Pharmaceutical Research and Manufacturers of America (PhRMA) and Biotechnology Industry Organization (BIO) took the position that even minor changes in the manufacturing process can have a "potentially profound clinical impact".[19] The unintended consequences of this innovator industry position with respect to enablement of biological patents are discussed later in this chapter.[20] Therefore, these diametrically opposing views taken by the brand and generic industries with respect to biosimilars can be expected to result in considerable and extended patent litigation between these two segments of the pharmaceutical industry, as has been witnessed with litigation between these two entities under the 1984 Hatch-Waxman Act. A more exhaustive discussion of the history of the passage of the BPCI can be found elsewhere.[21] It also provides insights into the legal battles expected to come between and among the FDA and innovator and generic companies.

## 5.3 APPROVAL GUIDELINES FOR A GENERIC BIOLOGICAL PRODUCT

The FDA, which has been delegated the authority to develop appropriate rules and guidelines for the approval of biosimilars,[22] has yet to provide these details; they are expected in fiscal year 2013.[23] Although optional,[24] in February 2012, the agency provided three preliminary science-oriented guidance documents under the familiar major heading "Guidance for Industry." These "Draft Guidance" documents have the following self-explanatory subtitles: (1) "Biosimilars: Questions and Answers Regarding Implementation of the Biologics Price Competition and Innovation Act of 2009,"[25] (2) "Quality Considerations in Demonstrating Biosimilarity to a

Reference Protein Product,"[26] and (3) "Scientific Considerations in Demonstrating Biosimilarity to a Reference Product."[27] The practical implications of these recommendations for biosimilars manufacturers will crystallize only after the FDA issues its final rules.

The BPCI Act defines a generic biological product as a biosimilar[28] or an interchangeable.[29] The fact that an interchangeable biosimilar can be substituted for a reference product without the knowledge or consent of the prescriber could raise a conflict between state and federal laws on drug substitution. Currently, in most (if not all) states, generics for small molecule drugs cannot be substituted for the reference product if the prescriber checks the "Dispense as written" box on the prescription. It would appear that state pharmacy laws may have to be modified for interchangeable biosimilars because the dispenser, most likely a pharmacist, can under the BPCI Act make a substitution without the consent or knowledge of the prescribing physician. Some states have moved to remedy this uncertainty (see Section 5.6).

An applicant for a biosimilar product is required to provide the following supportive evidence:

1. Analytical data in support of similarity[30]
2. Preclinical (animal) studies[31]
3. Extensive clinical data[32]

[26] Food and Drug Administration. Guidance for industry: quality considerations in demonstrating biosimilarity to a reference protein product; 2012. Available from: http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/UCM291134.pdf.

[27] Food and Drug Administration. Guidance for industry: scientific considerations in demonstrating biosimilarity to a reference product; 2012. Available from: http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/UCM291128.pdf.

[28] "The term 'biosimilar' or 'biosimilarity'... means-(A) the biological product is highly similar to the reference product notwithstanding minor differences in clinically inactive components; and (B) there are no clinically meaningful differences between the biological product and the reference product in terms of safety, purity, and potency of the product" (42 U.S.C. § 262(i)(2)).

[29] "The term 'interchangeable' or 'interchangeability' in reference to a biological product that is shown to meet the standards [for a reference product] means the biological product may be substituted for the reference product *without the intervention of the health care provider who prescribed the reference product*" (emphasis added) (42 U.S.C. § 262(i)(3)).

[30] "[A]nalytical studies demonstrat[ing] that the biological product is *highly similar* to the reference product, not withstanding minor differences in clinically inactive component" (emphasis added) (42 U.S.C. § 262(k)(2)(A)(i)(I)(aa)).

[31] "[A]nimal studies (including the assessment of toxicity)" (42 U.S.C. § 262(k)(2)(A)(i)(I)(bb)).

[32] "[A] clinical study or studies (including the assessment of immunogenicity and pharmacokinetics or pharmacodynamics) that are sufficient to demonstrate safety, purity, and potency in 1 or more appropriate conditions of use for which the reference product is licensed and intended be used and for which licensure is sought for the biological product" (42 U.S.C. § 262(k)(2)(A)(i)(I)(cc)).

4. Mechanism of action data, when such information is known for the reference product[33]
5. Labeling information consistent with that approved for the reference product[34]
6. Route, dose, and dosage form information[35]
7. Assurance the manufacturing facility meets quality assurance standards[36]

An applicant is also required to provide information regarding the safety and efficacy of the reference product,[37] which the FDA makes public. The BPCI Act provides the applicant an option to provide additional publically available supportive information regarding the reference product or other, presumably related, products.[38]

An interchangeable biosimilar must, in addition to meeting the above requirements for a biosimilar product, also provide evidence that:

1. It produces the same clinical outcome.[39]
2. Under chronic use, the interchangeable product will be similar to the reference product in terms of safety and tolerance.[40]

It is not clear why there are two types of biosimilars, namely interchangeable and non-interchangeable biosimilars. Because the requirements for a biosimilar ensure similarity in outcome and almost all innovator biologicals and their corresponding biosimilars are more often than not administered "more than once," the additional (and confusing) requirements for interchangeability appears clinically unnecessary.[41]

[33] "[T]he biological product and reference product utilize the same mechanism or mechanisms of action for the condition or conditions of use prescribed, recommended, or suggested in the proposed labeling, but *only* to the extent the mechanism or mechanisms are known with the reference product" (emphasis added) (42 U.S.C. § 262(k)(2)(A)(i)(II)).

[34] "[T]he condition or conditions of use prescribed, recommended or suggested in the labeling proposed for the biological product have been previously approved for the reference product" (42 U.S.C. § 262(k)(2)(A)(i)(III)).

[35] "[T]he route of administration, the dosage form, and the strength of the biological product are the same as those of the reference product" (42 U.S.C. § 262(k)(2)(A)(i)(IV)).

[36] "[T]he facility in which the biological product is manufactured, processed, packed or held meets standards designed to assure that the biological product continues to be safe, pure, and potent " (42 U.S.C. § 262(k)(2)(A)(i)(V)).

[37] "An application . . . shall include publically-available information regarding the Secretary's previous determination that the reference product is safe, pure, and potent" (42 U.S.C. § 262(k)(2)(A)(iii)(I)).

[38] "[The applicant] may include any additional information in support of the application, including publicly-available information with respect to the reference product or another biological product." (42 U.S.C. § 262 (k)(2)(A)(iii)(II)).

[39] "[It] can be expected to produce the *same* clinical result as the reference product in any given patient" (emphasis added) (42 U.S.C. § 262(k)(4)(A)(ii)).

[40] "[F]or a biological product that is administered more than once to an individual, the risk in terms of safety or diminished efficacy of alternating or switching between use of the biological product and the reference product is *not greater* than the risk of using the reference product without such alternation or switch" (emphasis added) (42 U.S.C. § 262(k)(4)(B)).

[41] *Id.*

## 5.4 INTELLECTUAL PROPERTY PROTECTION UNDER THE BPCI ACT

The innovator enjoys dual monopolies for a limited time, which run in parallel. The first one is the protection afforded by market exclusivities. The second is via the traditional patent protection. Such dual IP protection is provided to incentivize innovation and marketing of new biological products.

### 5.4.1 Market Exclusivities

The reference product innovator is allowed an exclusivity period of 12 years from the date of approval.[42] This exclusivity does not apply to a supplement of the original reference product[43] or "to a subsequent application . . . for a change (not including a modification to the structure of the biological product) that results in a new indication, route of administration, dosing schedule, dosage form, delivery system, delivery device or strength"[44] or to a subsequent application . . . for "a modification to the structure of the biological product that does not result in a change in safety, purity or potency."[45] It appears that for these changes, the sponsor will have to seek patent protection and include them under the provisions provided to add newly issued or licensed patents[46]. In addition, as with the Hatch-Waxman Act, an additional 6 months of exclusivity is allowed if the innovator applicant provides clinical data in pediatric subjects.[47]

Furthermore, a generic product applicant is prohibited from filing an application for 4 years after the approval of the reference product.[48] From a practical standpoint, unless the FDA approval takes more than 8 years, this provision does not appear to be of additional benefit to the innovator given the 12-year market exclusivity.

There are incentives for the first manufacturer to market an interchangeable product with respect to the reference product. The first marketed generic

[42] "Approval of an application [for a generic biological product] may not be made effective by the Secretary until the date that is 12 years after date on which the reference product was first licensed" (42 U.S.C. § 262(k)(7)(A)).
[43] 42 U.S.C. § 262(k)(7)(C)(i).
[44] 42 U.S.C. § 262(k)(7)(C)(ii)(I).
[45] 42 U.S.C. § 262(k)(7)(C)(ii)(II).
[46] 42 U.S.C. § 262(l)(7).
[47] "If, prior to the approval of an application that is submitted [by the generic applicant] . . . the Secretary determines that information relating to the use of a new biological product in the pediatric population may produce health benefits in that population, the Secretary makes a written request for pediatric studies (which shall include a timeframe for completing such studies), the applicant *agrees* to the request, such studies are completed using appropriate formulations for each age group for which the study is requested within any such timeframe, . . . the periods for such biological product . . . are deemed to be . . . 12 years and 6 months. . . . " (emphasis added) (42 U.S.C. § 262 (m) (2)(A)).
[48] An application [for a generic product] may not be submitted for 4 years after the date on which the reference product was first licensed. . . . " (42 U.S.C. § 262(k)(7)(B)).

interchangeable biological product is granted one of several exclusivity protections, with the provision that the earliest of these protections applies:

1. A second or subsequent interchangeable product cannot be approved for sale for 1 year from the marketing of the first.[49]
2. When patent infringement action is brought against the first applicant for an interchangeable product, the exclusivity period is 18 months[50] after a final court decision[51] or "dismissal with or without prejudice of [patent infringement] action."[52]
3. The exclusivity period is 42 months after the approval of the first interchangeable product if patent litigation against the applicant is still ongoing.[53]
4. If the applicant is not sued, then the exclusivity period is 18 months from the approval of the first interchangeable product.[54]

### 5.4.2 Patent Protection and Infringement Issues

The BPCI Act appears to discourage patent litigation, as indicated by its provisions, which are quite different from those of the 1984 Hatch-Waxman Act. One big difference is that under this earlier act, the innovator asks the FDA to list all patents relevant to the innovator drug in the "Orange Book"[55] at the time of filing a New Drug Application (NDA). These relevant patents are called "sponsor patents." The generic drug applicant has the option to challenge these patent(s) on the basis of invalidity or non-infringement. Under the BPCI Act, there is no such listing of sponsor patents. Instead, the reference sponsor and the generic applicant are required to engage in lengthy prelitigation negotiations; included in these negotiations are technologies the sponsor is willing to license to the generic applicant. By the same token, the applicant is not required to accept these offers. Obviously, this provision is an attempt to minimize possible patent infringement litigation. This Act also limits the number of patents that can be litigated. These matters will be discussed in detail later in this section.

The patent negotiation process begins after the generic applicant is notified by the Secretary of Health and Human Services that the application has been accepted for review. Within 20 days after such notice,[56] the applicant must provide the reference product sponsor with information relating to the application and details of the

[49] 42 U.S.C. § 262(k)(6)A.
[50] 42 U.S.C. § 262(k)(6)B(i).
[51] "... the term 'final court decision' means a final decision of a court from which no appeal (other than a petition to the United States Supreme Court) for writ of certiorari has been or can be taken)." (42 U.S.C. § 262 (k)(6)).

[56] "Not later than 20 days after Secretary notifies ... the applicant that the application has been accepted for review, the applicant shall provide the sponsor..." (42 U.S.C. § 262 (l)(2)).

manufacturing process(es)[57] and may optionally provide other information sought by the sponsor.[58] It does not appear there are any incentives for the applicant to comply with this last provision. After receipt of this information from the applicant for a biosimilar or an interchangeable product, the reference product sponsor shall provide the applicant with a list of relevant patents[59] and offers and licensing options, if any, within 60 days.[60] Reminiscent of Hatch-Waxman provisions,[61] the applicant has 60 days to respond to the sponsor addressing issues relating to invalidity and unenforceability of the listed patents or non-infringement of these patents by the applicant. In addition, the applicant should provide the sponsor with a response to its offer of licensing.[62] Interestingly, there is an optional self-incriminatory provision in which the applicant can admit to innovators' patents that it is likely to infringe.[63] Again, it does not appear the applicant has any incentive to respond to this option.

### 5.4.3 Patent Negotiations and Litigation Phase

Negotiations begin after the exchange of correspondence between the applicant and the sponsor regarding the validity, enforcement, or infringement of patents submitted by the sponsor. The two parties "shall engage in good faith negotiations to agree on which, if any, of the listed patents by the . . . applicant or the . . . sponsor shall be the subject of an action for patent infringement. . . ."[64]. If there is non-agreement between the parties within 15 days of negotiations, the next step is litigation.[65]

Before the start of litigation, the applicant for the generic biological product shall notify the reference product sponsor with the number of patents the applicant will submit to the sponsor.[66] This is the second chance for the applicant to provide such information to the sponsor, except that this time, it is not optional as in the first time.

[57] "[T]he applicant shall provide to the reference product sponsor a copy of the application submitted, . . . and other such other information that describes the process or processes used to manufacture the biological product. . . ." (42 U.S.C. § 262(l)(2)(A)).

[58] The applicant "*may* provide to the . . . sponsor additional information requested by or on behalf of the sponsor" (emphasis added) (42 U.S.C. § 262(l)(2)(B)).

[59] ". . . the . . . sponsor shall provide the . . . applicant a list of patents for which the . . . sponsor believes a claim of patent infringement could reasonably be . . . asserted by the . . . sponsor . . ." (42 U.S.C. § 262 (l) (3) (A) (i).

[60] ". . . an identification of the patents on such list that the . . . sponsor would be prepared to license to the . . . applicant." (42 U.S.C. 262(l)(3)(A)(ii)).

[61] Food and Drug Law and Regulation, Editors: Adams DG, Cooper RM, Hahn, MJ and Kahan JS, FDLI, Washington DC (2008), pp. 365–368.

[62] ". . . the applicant shall provide the . . . sponsor [with] a response [to patents the sponsor would be prepared to license], . . . under subparagraph (A)(ii)." (42 U.S.C. § 262(l)(3)(B)(iii)).

[63] ". . . the applicant may provide to the sponsor a list of patents to which the . . . applicant believes a claim of patent infringement could reasonably be asserted by the . . . sponsor if a person not licensed by the . . . sponsor engaged in making, using, offering to sell, selling or importing into the United States of the biological product that is subject of . . . the application" (42 U.S.C. § 262(l)(3)(B)(i)).

[64] 42 U.S.C. § 262(l)(4)(A).

[65] "If within 15 days of beginning negotiations, . . . the . . . applicant and the . . . sponsor fail to agree on a final and complete list of which, if any, patents listed . . . by the . . . applicant or the . . . sponsor shall be the subject of an action of patent infringement . . ." (42 U.S.C. § 262(l)(4)(B)).

[66] 42 U.S.C. § 262(l)(5)(A).

Note that the applicant is required only to submit the number of patents and not a list.[67] After this notification, further actions shall proceed as follows: On a mutually agreed date, but within 5 days after such notification by the applicant, the two parties shall "simultaneously exchange"[68] a list of patents. Such an exchange is a deterrent to modifying patents of interest, based on knowledge of the other party's patents. The list includes patents that each party believes are in contention.[69] The number of patents a sponsor can list cannot exceed the number of patents listed by the applicant.[70] If the applicant does not include any patents in its list, the sponsor is limited to a single (i.e., one) patent that can be litigated. The sponsor must initiate infringement action within 30 days, irrespective of the fact that the sponsor and the applicant have agreed[71] or not agreed[72] on the patent(s) to be litigated. The applicant must report and provide a copy of the complaint to the Secretary of Health and Human Services,[73] who makes it public knowledge.[74]

The sponsor is allowed to add newly obtained or licensed patents to the list (mutually agreed or not) within 30 days of obtaining such patents[75] with notification to the applicant. Upon receipt of this notification, the applicant shall, *inter alia*, inform the sponsor about the invalidity or non-enforceability of the added patent(s), or non-infringement of the new patent(s) by the applicant's product, or state that its product will not be marketed before the expiration of this newly added patent(s). This

[69] ".... the list of patents that the applicant believes should be the subject of an action for patent infringement..." (42 U.S.C. § 262(l)(5)(B)(i)(I)) and " the list of patents that the sponsor believes should be the subject of an action for patent infringement..." (42 U.S.C. Section § 262(l)(5)(B)(i)(II)).

[70] 42 U.S.C. § 262(l)(5)(B)(ii).

[71] "If...the...applicant and the...sponsor agree on patents...not later than 30 days after such agreement, the...sponsor shall bring an action for patent infringement with respect to each such patent." (42 U.S.C. § 262(l)(6)(A)).

[72] "If [the is failure to reach agreement between the parties]...not later than 30 days after the exchange of lists....the...sponsor shall bring an action for patent infringement with respect to each patent that is included in such lists" (42 U.S.C. § 262(l)(6)(B)).

[73] "Not later than 30 days after a complaint is served...to a[n] applicant in an action of patent infringement...the applicant shall provide the Secretary with notice and copy of such compliant." (42 U.S.C. Ï262 (l)(6)(C)(i)).

[74] "The Secretary [of Health and Human Services] shall publish in the Federal Register notice of a complaint..." (42 U.S.C. § 262(l)(6)(C)(ii)).

[75] "In the case of a patent that (A) is issued to, or exclusively licensed by, the...sponsor after the date that the...sponsor provided the list to the...applicant...and (B) the...sponsor reasonably believes that, due to the issuance of such patent, a claim of infringement could reasonably be asserted by the...sponsor if a person not licensed by the...sponsor engaged in making, using, offering to sell, selling, or importing into the United States the biological product that is the subject of the...application, and not later than 30 days after such issuance or licensing the...sponsor shall provide the...applicant a supplement to the list provided [earlier] by the...sponsor that includes such patent...." (42 U.S.C. § 262(l)(7)(A) and (B)).

part of the response by the applicant is identical to the response during earlier patent negotiations.[76]

The applicant is required to notify the sponsor within 180 days before proposed marketing of its generic product.[77] Upon such notice, the sponsor is allowed to seek a preliminary injunction[78] to stop the intended marketing until the matter is resolved in the courts.[79] The courts examine the relevant patents for validity, enforceability, and infringement by the generic applicant.[80] Both parties "shall reasonably cooperate to expedite such further discovery as is needed in connection with the preliminary injunction motion."[81]

Incentives are provided to the generic applicant to follow procedures provided in the BPCI Act. If the applicant provides the sponsor with a copy of the biosimilar application containing all of the details as described,[82] both parties are prohibited from bringing a declaratory judgment action[83] for patent infringement, validity, or enforcement until the generic applicant notifies the sponsor about its intent to market the generic.[84] This action applies only to patents that were presented by both parties during negotiations.[85] If the applicant fails to provide the sponsor with the applications, the penalties may be severe in that only the sponsor "may bring an action . . . for a declaration of infringement, validity or enforceability of *any* patent that claims the biological product or use of the biological product (emphasis added)."[86] Additional incentives are also provided for the applicant to comply with provisions of the BPCI Act relating to patents.[87] If the applicant fails to state that (1) each of the patents originally submitted by the sponsor, including any new patent(s), are either invalid

[76] The applicant "shall provide to the . . . sponsor . . . a detailed statement that describes, on a claim by claim basis, the factual and legal basis of the opinion of the . . . applicant that such a patent is invalid, unenforceable, or will not be infringed by the commercial marketing of the biological product. . . ." (42 U.S.C. § 262(l)(3)(B)(ii)(I)).

[77] "The . . . applicant shall provide notice to the . . . sponsor not later than 180 days before the date of the first commercial marketing of the biological product. . . ." (42 U.S.C. § 262(l)(8)(A)).

[78] An order from the court whereby the generic applicant is restrained from marketing the product. "An injunction commands an act that the court regards as essential to justice, or it prohibits an act that is deemed to be contrary to good conscience. It is an extraordinary remedy. . . ." TheFreeDictionary. Injunction. Available from: http://legal-dictionary.thefreedictionary.com/injunction.

[79] "After receiving [such] notice and before such date of the first commercial marketing of such biological product the . . . sponsor may seek a preliminary injunction prohibiting the . . . applicant from engaging in the commercial manufacture or sale of such biological product until the court decides the issue of patent validity, enforcement, and infringement with respect to any patent that is (i) included in the list provided by the . . . sponsor, [including newly issued or licensed patents] or in the list provided by the . . . . applicant . . . ) (42 U.S.C. § 262(8)(B)(i) and (ii)).

or unenforceable; (2) the marketed product will not infringe any of these patents; or (3) marketing of the applicant's product will not commence before the expiration of these patents or fails to notify the secretary of a notice of litigation, then the sponsor can immediately commence a declaratory judgment action with respect to validity, infringement, or enforceability of the pertinent patents.[88]

## 5.5 LEGAL ISSUES

One major legal issue focuses on a central question: How legal is the use of the sponsor's data by the FDA in approving a competitor's generic version of the sponsor's biological product? Clearly, the discretionary power of the FDA under the BPCI Act allows the agency to use innovator data for approval of biosimilars.[89] The anticipated litigation is most likely to focus on the extent of such use allowed by law. The following discussion provides some insight into these matters.

### 5.5.1 Food and Drug Administration Use of Sponsor's Data in Generic Biosimilar Approval

Trade secrets submitted by the reference sponsor under the Biologics License Application (BLA) are considered proprietary and protected by federal trade secret laws from disclosure. It is interesting to note that the FDA's definition of "trade secret" has evolved over the years. The current definition reads as follows: "A trade secret may consist of any commercially available plan, formula, process, or device that is used for the making, preparing, compounding, or processing of trade commodities, and that can be said to be the end of product innovation or substantial effort. There must be a direct relationship between the trade secret and the productive process."[90] The older definition included wording to protect unfair competitive edge.[91] This change was implemented after a court[92] refused to accept the agency's broader definition of a trade secret; it used a narrower definition, which was adopted by the FDA. Trade secrets are also protected from disclosure under the FDA's rules governing the Freedom of Information Act[93] and prohibited acts.[94] The FDA's past decisions also support the belief that information is proprietary.[95] In one case, a

[88] 42 U.S.C. § 262(l)(9)(B) and (C).
[89] 42 U.S.C. § 262(k)(2)(ii).
[90] 21 C.F.R. § 20.61(a).
[91] "A trade secret may consist of any formula, pattern, device, compilation of information which is used in business, and gives him an opportunity to obtain an advantage over competitors who do not know it or use it," 21.C.F.R. 20.61(a) (1982).
[92] Pub. Citizen Health Research Group v. FDA, 704 F.2d 1280 (D.C. Cir., 1983).
[93] 21 C.F.R.§ 20.61(c) .
[94] "The using by any person to his own advantage or revealing, other than to the Secretary or officers or employees of the Department, or to the courts when relevant in any judicial proceeding under this Act, any information acquired . . . concerning any method or process which is a trade secret is entitled to protection; . . . " (21 U.S.C. § 331(j)).
[95] *Tri-Bio Lab., Inc. v. United States,* 836, F.2d 135, 141.

manufacturer asked FDA to approve its generic version of a veterinary drug by incorporating information submitted earlier by the innovator for the same drug. The FDA refused to consider the application based on "its policy [of] treating such information as proprietary and confidential."[96] The court agreed with the agency's decision. But this court made the distinction that internal use of data provided by the reference sponsor to approve a generic product does not constitute disclosure.[97]

It would be informative, and perhaps also predictive of FDA's approach to biosimilar approvals, to examine certain provisions of Section 505(b)(2) of the Federal Food, Drug, and Cosmetic Act, under which biologicals have been approved. These provisions are quite similar to those of the BPCI Act in that it allows a later applicant to rely on a previous (innovator) applicant's safety and efficacy data. It should be noted that a 505(b)(2) application is considered a new drug application. Section 505(b)(2) states:

> An application [may be] submitted under . . . section 505 (b)(2)for a drug for which the [safety and effectiveness] investigations . . . relied upon by the applicant for approval of the application were not conducted by or for the applicant and for which the applicant has not obtained a right of reference or use from the person by or for whom the investigations were conducted . . . and [shall] also include . . . a certification to each patent which claims the drug for which such investigations were conducted or which claims a use for such drug for which the applicant is seeking approval.

A couple of examples are presented to illustrate the nature of innovator challenges to the FDA regarding such reliance. One case involved the potential marketing of amlodipine maleate (Amvaz) by Dr. Reddy's Laboratories under the Section 505(b)(2) paradigm. This applicant chose to rely on Pfizer's NDA, which was for the besylate salt of amlodipine (Norvasc). Pfizer filed a Citizen Petition asking the FDA to "immediately revoke its acceptance for filing and receipt of [the application] and/or deny [it's] approval" on the argument that FDA could not approve the Amvaz application using the Norvasc NDA application because that would constitute unauthorized use of proprietary information. In response, Dr. Janet Woodcock, director of the Center of Drug Evaluation Research, denied the petition and stated that no proprietary information is used in Section 505(b)(2) decision making.[98]

Other innovator companies have also petitioned the FDA challenging information sharing under a Section 505(b)(2) application. In a second instance, Genentech petitioned the FDA to "refrain from taking steps that prejudice [Genentech's]

[96] "Any reference to information furnished by a person other than the applicant may not be considered unless its use is authorized in a written statement signed by the person who submitted it," 21 C.F.R. § 514.

[97] "Because the Trade Secret Act . . . prohibits only public disclosure of application data, it does not bar internal agency use of submitted data," *Tri-Bio Lab., Inc. v. United States,* 836, F.2d 135, 141.

[98] "FDA may rely on its earlier conclusions regarding safety and effectiveness to whatever extent the conclusions are appropriate for the drug under review in the 505(b)(2) application. Although reliance of an FDA finding of safety and effectiveness for an NDA is certainly indirect reliance on the data submitted in the original NDA, reliance on the conclusions supported by that data is not the same as manipulating those data to reach new conclusions not evident form the existing approval," Docket No. FDA-2003-P-0014.

property rights in trade secret and confidential commercial data and information provided by the agency for the limited purpose of reviewing and approving [Genentech's'] products."[99] In the matter of the Omnitrope application filed by Sandoz, the petitioner (Pfizer) raised both scientific and legal concerns. Of interest to the discussion here are the legal aspects of the challenge: In its petition, Pfizer stated: "It is . . . legally improper for FDA to rely on, reference, or otherwise use the clinical and manufacturing information that establishes the safety and effectiveness of Genotropin . . . to approve Omnitrop[e]." In a collective response to several petitioners, the FDA did not address the issues relating to ". . . . the legality of relying on the approval or licensing of another product to approve or license follow-on protein products, . . . [t]rade secret and Constitutional law (Fifth Amendment takings clause) arguments based on the use of trade secret data and information (e.g., chemistry, manufacturing, and controls (CMC)) data in one approved application to review and approve another application for a follow-on protein product . . ."[100] and stated that "the FDA has not and does not need to review or use any trade secret information from the approved Genotropin application, or any other application, to approve the Omnitrope NDA."[101] In its lengthy explanation in support of denial, the agency also provided a broader assurance to the petitioner that it had "not compromised the protections offered under the law to [innovative] data and information."[102]

Citing two provisions of the BPCI Act, one author has concluded that "[t]he question whether FDA is authorized to examine and consider the information in the reference product application, when reviewing biosimilar applications should therefore be regarded as fully settled by the statute itself: FDA may not do so."[103] One of the provisions is the requirement that the applicant can only use nonproprietary information in its application. The second one is that the FDA can only use "the information submitted in the application (or a supplement)" in its decision making. To add to the debate, another commentator, citing a 2005 article, stated: "A follow-on biologic manufacturer must use the pioneer biologic's manufacturing process to demonstrate interchangeability. . . ."[104] There is no such assertion in the BPCI Act; whether it is a biosimilar or an interchangeable, the requirements are that ". . . . the facility in which the biological product is manufactured, processed, packed, or held, meets standards designated to assure that the biological product continues to be safe, pure and potent."[105]

[105] 42 U.S.C. § 262(k)(2)(A)(V).

With regard to the assertion,[106] the history of generic approval legislation and implementation shows FDA reliance on innovator information. This is reflected in the agency's response to the Omnitrope and other petitions. It appears that the agency will not respond to legal matters, leaving such challengers no option but the courts. This might be because the FDA believes it can win in court because of the agency favorable Supreme Court decision in the *Chevron*[107] case.

The Court held the following: "First, always, is the question whether the Congress has spoken directly to the precise question at issue. If the intent of Congress is clear, that is the end of the matter; for the court, as well as the agency, must give effect to the unambiguously expressed intent of Congress. . . . if the statue is silent or ambiguous with respect to a specific question, the issue for the court is whether the agency's answer is based on a permissible construction of the statute."

The phrase any "permissible construction" of the law is indeed a low threshold for the FDA to meet, if challenged. This might explain why Pfizer did not further contest the FDA's denial of its petition in the Omnitrope case (*supra*).

In one author's opinion, if anything is "settled,"[108] it is that the FDA can use and has used data submitted by the innovator in approving a competitor's generic product. The FDA has repeatedly stated that no proprietary information has or will be used. This remains a contentious issue between the industry and the agency.

***5.5.1.1 Takings Issue*** Concerns have been expressed regarding the possible use by the FDA of proprietary information submitted by innovator companies in the approval of biosimilars. Some specifics are discussed later (see Section 5.6). This section presents a brief summary of pertinent legal issues. The uncompensated use of an innovator's trade secret information may be unconstitutional under the Fifth Amendment of the United States Constitution.[109] Two Supreme Court cases have to be considered in analyzing the takings issue. In one case,[110] the Supreme Court ruled that if the law warns the sponsor that confidential information submitted for regulatory purposes will be disclosed, then there is no takings issue because the data was submitted voluntarily by the sponsor.[111] It appears that BPCI Act provides such notice, even if it is indirect.[112] The second issue deals with the matter of compensation. In the second Supreme Court case,[113] a similar regulatory situation involving the EPA had to deal with the agency using the sponsor's pesticide safety and efficacy data to approve a generic version. Because the Federal Insecticide, Fungicide, and Rodenticide Act required generic manufacturers to compensate the sponsor, the Supreme Court ruled that this Act did not violate the takings clause.

[106] Epstein (*supra*).
[107] *Chevron U.S.A. Inc. v. Natural Resources Defense Council, Inc.*, 467 U.S. 837 (1984).
[108] Epstein (*supra*) at 294.
[109] "... nor shall private property be taken for public use, without just compensation."
[110] *Penn Central Transportation Co. V. City of New York,* 438 U.S. 104, 124 (1978).
[111] This is a disingenuous argument because the sponsor has no choice but to submit the required data for market approval.
[112] 42 U.S.C. § 262(k)(2)(A)(ii).
[113] *Ruckelshaus v. Monsanto Co.,* 467 U.S. 986, 1000-01 (1984).

Given the long history of the approval of drugs and biologicals, it appears that court challenges on the takings would favor the FDA. As noted, that might be the reason why Pfizer did not challenge the agency's denial of its Omnitrope petition (*supra*). In addition, it could be argued that market exclusivities under the BPCI Act provide just compensation for use of an innovator's trade secret by the FDA to approve a generic.

***5.5.1.2 Lack of Patent Enablement*** This is a second legal issue for biological products in general. Brand name companies, by their statements about the general inabilities of generic companies to produce biosimilars, may have inadvertently raised the issue of enablement, with respect to validity of existing biological patents and future patentability of biologicals.[114] Patent law requires that any patent for a product (in this case, a biological) disclose sufficient information for a skilled individual to be able to manufacture that product (i.e., enablement).[115] In addition, "undue" experimentation on the part of this skilled individual to make the biological product would not meet the enablement requirement.[116] The *Genentech, Inc. v. Novodisk* case involved the validity of US Patent 5,424,199, which deals with a recombinant human growth hormone. This patent was declared "invalid for failure of the specification to meet the enablement requirement . . . "[117]

***5.5.1.3 Safe Harbor Provisions*** This issue is related to patent infringement. It is not clear if the "safe harbor" provisions under the Hatch-Waxman Act, which apply to small molecule drugs, would also apply to biologicals. Under these provisions, a generic drug manufacturer is allowed to use patented information without infringement for preparing its Abbreviated New Drug Application (ANDA) filing to the FDA.[118] A strict reading of the statutory language suggests that these provisions may not apply to biosimilars. However, before the passage of the BPCI Act, proteins, now included in the definition of a biological product, had been approved under the

[114] Mandel GN. The generic biologics debate: industry's unintended admission that biotech patent fail enablement. Virginia J. Law & Tech. Vol. 11, No. 8 , 1-25, Fall 2006.

[115] "The specification shall contain a written description of the invention, and of the manner and process of making and using it, in such full, clear, concise, and exact terms as to enable any person skilled in the art to which it pertains, or with which it is most nearly connected, to make and use the same, and shall set forth the best mode contemplated by the inventor of carrying out his invention," 35 U.S.C. § 112 Specification (1994).

[116] In re Vaeck, 947, F.2d 488 (Fed. Cir., 1991).

[117] 108 F.3d 1361, 1368.

[118] "It shall not be an act of infringement to make, use, offer to sell, or sell within the United States or import into the United States a patented invention (other than a new animal drug or veterinary biological product (as those terms are used in the Federal Food, Drug, and Cosmetic Act and the Act of March 4, 1913) which is primarily manufactured using recombinant DNA, recombinant RNA, hybridoma technology, or other processes involving site specific genetic manipulation techniques) *solely* for uses reasonably related to the development and submission of information under a Federal law which regulates the manufacture, use, or sale of drugs or veterinary biological products." (emphasis added) (35 U.S.C 271(e)(1)).

FDCA (Food, Drug, and Cosmetic Act), blurring the difference between these two classes of therapeutic agents. Furthermore, similarities in statutory definitions of a drug[119] and biological product[120] are not helpful in resolving this issue.

A recent decision by the Federal Court of Appeals involving the generic version of the anticoagulant drug Lovenox (generic name, enoxaparin) would suggest that biosimilar manufacturers may also be protected under these provisions.[121] Enoxaparin, similar to many biologicals, is not a single entity; it consists of a mixture of oligosaccharides of varying molecular weights and compositions derived from the chemical breakdown of the complex drug heparin (itself a mixture of polysaccharides of different molecular weights and compositions) obtained from pig intestines. Momenta is the assignee of a patent[122] that is directed toward measurement of sulfated polysaccharides of varying molecular weights. Amphastar had used technology covered by this patent in preparing its FDA filing (i.e., ANDA) for approval for its generic version of Lovenox. Two days after the FDA approved Amphastar's generic version, Momenta, which markets its own generic version of Lovenox, filed a patent infringement suit against Amphastar.[123] The district court ruled that Amphastar had infringed Momenta's patent and granted Momenta a preliminary injunction, thus preventing market entry of Amphastar's generic version of Lovenox. Amphastar appealed, arguing that the district court had taken "an unduly restrictive view of the safe harbor... [provisions] of 35 U.S.C. § 271(e)(1)."[124] The appeals court ruled that these provisions protect both pre- and postapproval activities. Preapproval activities relate to information use of patented information to prepare an ANDA, and postapproval activities refer to the use of the patented information after the ANDA is granted. For continued marketing of its generic product, "Amphastar is required [by the FDA] to conduct a laboratory determination of the identity and strength of the active ingredient for each batch of enoxaparin."[125] Therefore, the appeals court concluded that Amphastar's postapproval activities were covered by the safe harbor provisions because "[h]ere, the submissions are not 'routine submissions' to the FDA..."[126] In a previous case, this court had ruled that these safe harbor provisions "[do] not apply to information that may be routinely reported to the

[119] Drugs are defined as "...articles intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease in man or other animals" or " articles (other than food) intended to affect the structure or any function of the body of man or other animals...." (21 U.S.C. § 321(g)(1)).

[120] A "biological product" is defined as a "virus, therapeutic serum, toxin, antitoxin, vaccine, blood, blood component or derivative, allergenic product, protein (except any chemically synthesized polypeptide) or analogous product, or arsphenamine or derivative of arsphenamine (or any other trivalent organic arsenic compound) applicable to the prevention, treatment, or cure of a disease or condition of human beings," 42 U.S.C. § 262(i)(1).

FDA, long after marketing approval has been granted."[127] Upon the advice of the Solicitor General of the United States, the Supreme Court denied a petition for certiorari (i.e., to hear the case) in the *Classen* case. Stay tuned. This matter is not over. Momenta plans to appeal the federal circuit decision to the Supreme Court.[128]

## 5.6 FUTURE PERSPECTIVES

This concluding section presents several important and unresolved issues littering the biosimilar IP landscape. In this author's opinion at this time (February 2013), the major uncertainties facing innovator and prospective biosimilar manufacturers can be grouped under three major headings: regulatory, legal, and political. From a regulatory perspective, it was only recently (*supra*) that the FDA started providing preliminary regulatory and scientific guidances to the industry for biosimilar approval under the BPCI Act. As might be expected given the complexity of biological drug products (compared with small molecule drugs), the FDA will initially take a "case-by-case" approach to approval of biosimilar products. Understandably, it will take several years for the various stakeholders connected with the biotechnology and pharmaceutical industries, especially marketers of innovator and generic products, to fully understand the FDA's regulatory enforcement scheme and to develop strategies for individual success in a profit-driven environment. Given the high cost of biological product development, the amount of nonclinical and clinical information required by the FDA of a prospective biosimilar applicant to prove similarity or interchangeability to an innovator product will be one big deciding factor for market introduction of biosimilars. If such requirements are deemed excessive vis-à-vis profitability by the industry, obviously biosimilar development will be adversely affected.

A second matter pending before the FDA relates to the constitutionality of the use innovator data by the FDA to approve generics. The Citizen Petition filed by Abbott Laboratories on April 2, 2012, asserts that the BPCI Act does not apply to innovator biologicals filed before the passage of this act on March 10, 2010. The petition asks the FDA to:

> [C]onfirm that it will not accept for filing, file, approve, or discuss with any company, or otherwise take any action indicating that the agency will consider, any application or any investigational new drug application (IND) for a biosimilar that cites, as its reference product, BLA 125057 for Humira® (adalimumab) or any other product for which the biologics license application (BLA) was submitted to FDA prior to March 23, 2010, the date on which the BPCIA was signed into law.[129]

[127] *Classen Immunotherapeutics, Inc. v. Biogen IDEC,* 659 F.3d 1057, 1070 (Fed. Cir., 2011).

[128] Momenta. U.S. Court of Appeals denied Momenta Pharmaceuticals petition for rehearing en banc in "safe-harbor" case; 2012. Available from: http://ir.momentapharma.com/releasedetail.cfm?releaseid=722630.

[129] Abbott Laboratories Covington and Burling LLP Citizen petition, FDA Docket No. 2012-P_0317. Available from: http://www.regulations.gov/#!documentDetail;D=FDA-2012-P-0317.

Because Abbott "had no notice, or reasonable expectation, that the agency would use its trade secrets to approve another company's product," when the BLA for Humira was submitted to the FDA in 2002, the company believes that such uncompensated use would be unconstitutional under the Fifth Amendment[130] (issue discussed earlier). As of October 1, 2012, the FDA had not decided on this petition.[131] Given the importance of this issue, it is very likely that any decision by the FDA will be legally challenged. In this connection, it is interesting to note the Patient Protection and Affordable Care Act, which includes the BPCI Act, was found constitutional by the Supreme Court.[132] This could weaken the takings argument.

Another regulatory challenge for the FDA is for an applicant to take a "short cut" to biosimilar approval by filing it as 351(a) application, where it would enjoy the benefits of an abbreviated filing of a 351(k) application; such filings have been referred to as "skinny BLAs."[133] There is some evidence in support of such a strategy. Teva admits that its product, Neutroval (a granulocyte colony-stimulating factor) is a biosimilar to Neupogen, marketed by Amgen. However, Teva filed a 351(a) application. The FDA claims it has no authority to prevent such filings,[134] but others have insisted that the agency does have such authority.[135] It is anticipated that the debate on this subject will continue, especially if others also chose such filings to bypass the BPCI Act.

The legality of "reverse payments," in which a generic company agrees not to compete with an innovator until its patents have essentially expired, is also an unresolved matter of general interest to the drug and biotechnology industries. The Federal Trade Commission (FTC) has estimated that such "pay for delay agreements" will cost "American consumers $3.5 billion per year—$35 billion over the next 10 years."[136] After disagreements between the Third[137] and Eleventh[138] Circuit Courts, the Supreme Court heard, on March 25, 2013, oral arguments on the question posed by petitioner FTC in its brief[139]: "Whether reverse-payments are per se lawful unless the underlying patent litigation was a sham or the patent was obtained by fraud, or instead are presumptively anticompetitive and unlawful?" The Supreme Court ruled on June 17, 2013 that reverse payments are in violation of

antitrust laws (FTC v. Actavis, Inc., 570 U.S. ____2013). Therefore, innovator companies would find it difficult to delay the entry of biosimilars into the market through pay for delay arrangements with generic manufacturers.

Because biological products are often derived from natural substances, it has raised a fundamental question: Do they meet the legal requirements of patentability?[140] The "hot" debate over the patentability of naturally occurring substances (e.g., genes) has finally reached the Supreme Court. On April 15, 2013, it heard oral arguments on the question "Are human genes patentable?"[141] in the famous *Myriad* case. The trial court had ruled that the *BRAC1* and *BRAC2* genes (and perhaps, genes in general) are not patent-eligible subject matter;[142] this decision was reversed by the Federal Court of Appeals, which maintained that isolated genes are patentable.[143] A second question for arguments heard on April 15 was "Did the court of appeals err in upholding a method claim by Myriad that is irreconcilable with [the Supreme] Court's ruling in Mayo Collaborative Servs. v. Prometheus Lab., 132 S. Ct. 1289 (2012)?" In the *Prometheus* case, the Supreme Court ruled that a diagnostic test involving measurement of 6-thioguanine in blood for possible drug dosage adjustment is not patentable subject matter. The Supreme Court decided on June 13, 2013 that isolated genes (genomic DNA) are not patentable because they are products of nature. However, complementary DNA, where introns have been removed from the DNA, is patentable. The impact of this much awaited decision on biologicals remains to be seen. One recent commentary (Rai et al., Science, 341, 137–138, 2013 (July 12)) stated that the impact of this decision can be expected to be "modest", since "[many] human gDNA patents have expired or will do so soon."

The general applicability of the safe harbor provisions to biological drug development, especially postapproval activities, remains unclear. The *Classen* and *Momenta* cases (*supra*) have let open the possibility of Supreme Court intervention, given statements made by the Solicitor General in the *Classen* case.[144]

Finally, a relatively new (political) hurdle for the biosimilar industry is state-level lobbying by innovator companies. Some of these companies (e.g., Genentech,

[140] 35 U.S.C. 101 "Whoever invents or discovers any new and useful process, machine, manufacture, or composition of matter, or any new and useful improvement thereof, may obtain a patent therefore, subject to the conditions and requirements of this title." 35 U.S.C. 101; "Laws of nature, natural phenomena, and abstract ideas are not patentable" Diamond v. Diehr, 450, U.S. 303, 309 (1981).

[143] Association for Molecular Pathology, et al., v. United States Patent and Trade Mark Office, 689 F.3d 1003 (August 16, 2012).

[144] "It is an open question whether Section 271(e)(1) applies at all to all patented research methods of the kind at issue in this case." Amicus Brief of the Solicitor General of the United States in the *GlaxoSmithKline v. Classen Immunotherapies, Inc.* at p. 20. Available from: http://www.justice.gov/osg/briefs/2012/2pet/6invit/2011-1078.pet.ami.inv.pdf.

Eli Lilly) have initiated efforts in Virginia, North Dakota, and Indiana to reduce biosimilar market share by limiting the ability of pharmacists to make generic substitutions for innovator biologicals.[145] Such efforts are being opposed by generic and insurance companies. Although early, both sides appear to have been successful. The Virginia House of Delegates passed such a law by a vote of 91 to 6, and the Indiana House Public Health Committee "approved a bill, but law makers responding to objections from the generic association, removed the requirement that the patient consent to any substitution." [146] Because, in general, patient consent will be dictated by price and biosimilars can be expected to less expensive (otherwise the very goal of the BPCI Act would be in vain), the need for such a requirement seems unwarranted. As a recent newspaper report put it, "The trench fighting at the state levels is the latest phase in a battle over the rules for adding competition to the biotechnology drug market. . . . "[147] As noted (*supra*), the BPCI Act allows for such substitution without the knowledge of the subscriber,[148] and state laws govern dispensing of drugs and biologicals.

In conclusion, it would not be surprising that there will be many regulatory challenges and much litigation as has been observed with approval of generics under the 1984 Hatch-Waxman Act; patent challenges under provisions of this Act increased fivefold between 2003 and 2009. To date, no application for a biosimilar has been submitted to the FDA.[149] However, ample incentives for biosimilar manufacturers will soon become available because biological patents worth an additional $47 billion in sales will expire between 2015 and 2020.[150] The impact of the BPCI Act on the biologicals industry will begin to crystallize only as the FDA starts to review and decide on applications for biosimilars and interchangeables and as patent and regulatory challenges are resolved by the courts.

# Scientific Aspects of Sterility Assurance, Sterility, Asepsis, and Sterilization

JAMES E. AKERS and JAMES P. AGALLOCO

## 6.1 INTRODUCTION

This chapter provides introductory-level information relating to sterile product manufacturing and the control of microbiological contamination in that endeavor. However, many of the principles discussed here are relevant to any process in which the control of microbiological contamination is paramount. Microbiology is a broad and intensely complex science, and unfortunately, novices often fail to grasp the complexity of the discipline and further fail to appreciate the diversity of the microbial world. So diverse are the organisms in the science of microbiology that they fall into two primary phylogenetic kingdoms, the prokaryotes and the eukaryotes. In fact, the incredible diversity of the microbial world is such that some organisms, viruses, are neither prokaryotes nor eukaryotes and instead are obligate intracellular parasites possessing genetic material and a limited complement of functioning enzymes but lacking any innate metabolic apparatus. Although in sterile product manufacturing, the focus is primarily on the bacterial and mycologic world (prokaryotes and eukaryotes), this is most assuredly not true in the case of some products of biological origin in which contamination with adventitious viruses could be problematic.

Fortunately, only a tiny percentage of the microorganisms with which we humans share the earth have shown any capability to produce disease. The overwhelming majority of organisms found on our bodies and in our environment are completely harmless commensals or even organisms with which humans have a symbiotic relationship.

## 6.2 CONTAMINATION CONTROL

In the control of microbial contamination, there are only two primary methods available. The manufacturer can use systems intended to prevent microbial contamination from entering the production pathway or it can use chemical or physical means in the form of heat, chemicals, or irradiation to kill microorganisms. Some manufacturing processes, of course, use a combination of microbial exclusion and microbial destruction. It is necessary for industrial microbiologists to have sufficient understanding both of processes for microbiological exclusion and destruction. Of course, it is also useful to understand environmental circumstances that favor microbial colonization or survival because, given the ubiquity of microbes in nature, complete exclusion of microbes is an impossible rather than merely a difficult task to accomplish.

## 6.3 FUNDAMENTAL CONCEPTS IN "STERILE" PRODUCT MANUFACTURING

Two separate, distinct, and very different methods are used to manufacture health care products that carry the word "sterile" on their labels. In the method called *terminal sterilization*, the product is sterilized in its final container before commercial release. Terminal sterilization performed with any reasonable degree of technical competence will result in a product that is very unlikely to be nonsterile, which is to say that each and every unit within a lot will be free of viable microorganisms. Terminally, sterilization will render any microbial contamination that might be present fully inert with a high degree of certainty. Importantly, this certainty is readily and very reliably quantifiable. The manufacturer can, with sufficient accuracy ensure reliability and reproducibility, measure the delivered lethality using thermographic data or some form of dosimetry depending on the method of sterilization used. So, it can be stated that precise analytical and monitoring methodologies can be applied to terminal sterilization, ensuring lot and unit sterility, and that these methods can be applied in process and during validation as required.

The second and more common method used in the manufacture of products labeled "sterile" is known as *aseptic processing*. As an industry, we would like to think that both terminal sterilization and aseptic processing attain the same endpoint, which, of course, is "sterility," and that both meet the regulatory expectation for the process control requirement that has come to be known as "sterility assurance." However, these two approaches, although aimed at the same apparent goal, have enormous differences obvious at both the practical and theoretical levels.

## 6.4 THE EVOLUTION OF ASEPTIC PROCESSING TECHNOLOGY

During a period that extended from the 1970s until the late 1980s, there was only one general method by which aseptic manufacturing was accomplished, and that was

using gowned human operators in large-scale classified suites of cleanrooms known as *aseptic processing areas*. It should be noted that during this period, there was considerable performance variability among aseptic processing operations relating to cleanroom design, the types of products manufactured, and the level of automation used. By the late 1980s, separative technologies such as isolators began to appear, and the past two decades have also seen dramatic increases in the capability of automation systems, further decreasing industry's reliance on personnel. Although there is solid evidence that aseptic processes have improved in terms of "sterility assurance," the health care industry is confronted with decisions and regulatory challenges that did not exist a quarter of a century ago.

Aseptic processing, although essential because of the large (and increasing) number of products that will not withstand terminal sterilization treatments, is a vastly more complex discipline than it was a comparatively short time ago. Among the reasons for this complexity are:

1. Multiple technologies in operation simultaneously: Industry at present is using conventional cleanrooms, isolators, restricted access barriers (RABs), and various combinations thereof with varying levels of automation.
2. There has never been a clear understanding within the regulations regarding what was possible in aseptic processing and perhaps more importantly what is impossible analytically. The idea that microbiological control when humans are involved is measurable in some quantifiable manner and therefore can be validated, although understandable in regulatory terms, is a scientifically formidable (and probably impossible) task.
3. There remains a poor understanding of the probabilistic nature of "sterility assurance" as it relates to process capability. There also exists an unfortunate tendency to believe that definitive means are available to prove that the state called sterility exists in each and every unit in each lot of product.
4. As a corollary to item 3, there is a persistent belief that it is possible to measure levels of sterility and know when sterility does or does not exist in a lot based on microbiological analytical methods. Although it may seem logical that methods used to detect microorganisms in a product or the environment should make the assessment of sterility possible, in reality, this capability continues to escape our grasp. The sheer diversity of microorganisms makes simple and easily applied assays for sterility a technical impossibility. Tests to prove sterility would require the ability to test each and every unit within a lot. This is of, course, both impractical and unrealistic. Testing of the environment is both statistically limited and unreliable and more significantly is not a direct test on the condition of the product but rather an assessment of transient contamination within the environment in which the product is made or assembled.
5. When confronted with concerns regarding the adequacy of growth-based analytical microbiological technology, there is the unfounded expectation that rapid or instrumental microbiological methods will obviate these uncertainties and actually allow for the measurement of "sterility." Sadly, there are

no instrumental methods on the horizon that could enable us to measure the sterility of individual units directly in a noninvasive or nondestructive manner. Hence, the advantage of rapid methods is largely speed of analysis as opposed to a lower limit of detection. The measurement of sterility would require an assay with perfect sensitivity combined with the ability to take a sample of infinite size. The technical challenge of proving the negative absolute that is sterility is an enormous one indeed; scientists and engineers working in this discipline must keep this in mind.

6. There is an expectation created by a combination of regulatory suggestion and vendor-generated "buzz" that genotypic microbial identification methods can provide a near infallible and therefore extremely reliable means of tracking down routes and sources of contamination. Reality in this case falls well short of perfection, and in fact, some rapid assays, because they are not growth based, make identification difficult or even impossible regardless of the identification method used. The contamination of an article with nucleic acid may be indicative of the presence of contaminants at some point in the manufacturing process; however, this does not mean that the material contains infectious organisms or microbial toxins. Certainly, in some investigations, genotypic identification has proven valuable; in others, it has provided no value. This is not surprising given the diversity of organisms among the microflora and the differences in distribution of these organisms that arise from multiple sources of contamination. Thus, there is no certainty that an airborne contaminant isolated from one environment may match an isolator recovered from filtration of the product. A single human operator may be colonized by multiple varieties of the same organisms. Vegetative cells released into an aseptic processing environment may not remain viable for more than a few hours, making the results of resampling activities uncertain.
7. New process control concepts are being added to the industry workload at an unprecedented rate. Concepts such as quality by design, process analytical technology, quality risk management, and various statistical process control methodologies may all have merit, but it is unclear how they apply to sterility assurance and how they correlate to preexisting and still required validation and monitoring programs. Readers are urged to consider each of these process control and management methodologies independently. Each of these concepts is sufficiently complex to require a complete chapter in and of itself. The minimization of risk in sterile product manufacturing requires that the product be safe, and this requires that the risk of microbial contamination in any product labeled sterile must be extremely low—in fact, lower than that of any other product type. That being said, the absolute elimination of microbiological risk in the administration of any product labeled "sterile" cannot be proven.

Although the concept of sterilization (or terminal sterilization of a finished product) in which a defined input for validation can be chosen and attained is

generally easier to understand, there are difficulties, both microbiological and statistical, that must be confronted. The mere fact that the term "sterility assurance," typically given as "sterility assurance level" (SAL), is applied to both exclusionary and lethal processes causes confusion. This has led to attempts to add the SAL results from aseptic processing and sterilization processes together. This seems quite reasonable mathematically given the apparent common unit of measure, but it is far from reasonable microbiologically.

## 6.5 STERILITY AND ASEPSIS: TOWARD A COMMON SCIENTIFIC UNDERSTANDING

It is clear in any discussion of sterility assurance that words really do matter and that when we talk of such things as viability, monitoring, sterile, sterilization, and aseptic, we have to be working from a common and well-accepted lexicon if we are to have any hope of reaching a broad and rather uniform level of understanding. These words appear in every regulatory standard, regulatory guidance document, industry standard, and international performance standard relating to sterile product manufacturing and those for microbiological controlled or restricted bioburden processes as well.

The authors have frequently asked training audiences to define two words that are used frequently the aforementioned documents, namely "aseptic" and "sterile." There have been a surprisingly wide range of definitions offered. Many individuals who attempt to define these words end up concluding that they are more or less synonymous. This could be because in many regulatory documents, the manner in which these words appear leads readers to conclude that in the regulatory context and therefore in practical usage, they are synonymous. In fact, the Food and Drug Administration's (FDA's) latest guidance document on aseptic processing contains the construction "sterile drug products produced by aseptic processing" in its title [1].

However, these words are not synonymous; there are very clear scientific distinctions between the words "aseptic" and "sterile." It is only when the real technical differences between the conditions these words describe are acknowledged that a path can be found to a more rational standard setting, regulation, and day-to-day process control.

Frequently, when the terms "sterile" and "aseptic" are under discussion, it is said that the differences in meaning between these words are not technically significant and therefore of only a semantic nature. One definition found in *Webster's New Collegiate Dictionary* for general semantics is "the language used in political propaganda or advertising to achieve a desired effect on an audience" [2]. However, "sterile" and "aseptic," when used in a regulatory sense, *should* be used with a clear and unambiguous *scientific* understanding. We must at all times avoid mistaking semantic conveniences for scientific fact.

If our industry is to have harmonized and universally applicable standards for products bearing the label "sterile," it is essential that we agree on a common lexicon.

Nearly a quarter of a century ago, the 1987 *FDA Guideline on Sterile Drug Products Produced by Aseptic Processing* implied in its title that aseptic processing can achieve a truly sterile result [3]. This construction was repeated in the title of the most recent version of this guideline published in 2004 [1]. This time interval should have been sufficient for thought to congeal around this fundamental concept of relatedness between "sterile" and "aseptic."

This implication of the confusion can be further examined by considering the definitions medical microbiologists apply to the word "sterile." Not surprisingly, although there is quite a lot of agreement on the meaning of the word "sterile," even the definition of this absolute term is not without conflict. In Jawetz et al.'s *Medical Microbiology*, "sterile" is defined as "Free of life of every kind. Sterilization may be accomplished by filtration (in the case of liquids or air) or by treatment with microbiocidal agents. Since the criterion of death for microorganisms is the ability to reproduce, sterile material may contain intact metabolizing microbial cells" [4]. It can be argued that the authors of this definition are having it both ways because they clearly state that "sterile" means free of life and then go on to define a condition in which metabolizing organisms are present. It is probably more reasonable to conclude that the authors have simply realized that the continuation of life requires the ability to reproduce. In fact, the term "sterile" is often applied to advanced multicellular organisms that lack the ability to reproduce.

However, one can clearly see the problem this definition poses for the detection of a "sterile" condition. If metabolic activity alone is not an indicator of non-sterility, does this not imply that test methods that rely on only biochemical activity cannot prove or disprove that living (reproducing) organisms are, in fact, present? Certainly, the condition defined as sterility cannot practically rule out the possibility that all evidence of the possible existence of microorganisms be absent from a preparation. Although there are few data on the subject, it is not unreasonable to think that genetic remnants of microorganisms lacking the ability to reproduce might indeed be present in a container labeled "sterile," perhaps even a material subjected to a sterilization process. Thus, it seems clear that a genetic screening method that yielded a signal but that does not allow the ability to discern whether the DNA came from a living or dead organism would not serve well as a "sterility" test. Certainly, such a signal might give useful information about potential contamination sources in an input material but could neither prove nor disprove "sterility."

Zinsser's *Medical Microbiology* text defines sterilization as "an absolute (term) that implies the total inactivation of all forms of microbial life in terms of the organism's ability to reproduce" [5]. These authors, perhaps wisely, steered clear of considerations regarding metabolic and simply based their definition upon the ability to reproduce.

*Microbiology* by Davis et al., a common text used in graduate microbiology and medical schools, defines "sterile" as "the use of either physical or chemical agents to eliminate all viable microorganisms" [6]. This definition avoids the debate about metabolism and growth but introduces the term "viability" instead. Fortunately, the authors do define viability, which they state is the "ability of the organism to

propagate indefinitely." Hence, their definition is again based on the ability of an organism to reproduce.

Although other microbiology texts and dictionaries offer slightly differing perspective regarding the definition of "sterility," all are in general agreement that the destruction of an organism's ability to replicate is central to the concept of sterilization and hence the attainment of the condition of "sterility." This is logical because it is quite clear that organisms that lack the ability to reproduce are incapable of causing an infectious disease, which, of course, is the risk modality by which microbial contamination produces adverse patient effect. Interestingly, it follows from this line of reasoning that viable but nonculturable organisms are in fact "sterile" unless they are actually put into conditions in which they can grow. It can be argued that the description "viable but nonculturable" is an oxymoron unless one expands the definition of "viable" to include metabolic activity, which is not justified, in the authors' opinion. Metabolic activity is an unreliable indicator of either the attribute of viability or the condition of "sterility." However, microbiologists are aware that an organism may fail to grow in one set of conditions (e.g., nutrition, oxygen level, incubation temperature) but grow quite well in other environmental circumstances. Does this mean that "sterility" can in fact be a conditional attribute? Yes; although this is a scientific reality, it is clear this is difficult from both a regulatory and legal perspective because it falls short of the expected (or hoped for) absoluteness.

## 6.6 STERILITY, VIABILITY, AND VIRULENCE

The ruling out of metabolic activity as an indicator of viability is essential. Among the microorganisms that are present in the environment and cause human and animal disease are a large number of obligate intracellular parasites, most notably viruses. Viruses are marvelously adapted parasites that lack any inherent metabolic activity and simply take over the metabolic and macromolecular synthesis machinery of their host in order to effect replication. Therefore, a material could be both free of detectable growth on all bacterial or mycological media and have no metabolic activity and still be "nonsterile."

In pure scientific terms, whereas a sterile product is one that contains no organisms capable of reproducing, an aseptically produced product is one that will not produce infection. An aseptically produced product may be sterile in the strictest sense, or it may not; however, at all times, it is expected to be noninfectious.

If we consider the term "sterility" a bit more critically, while properly an absolute, in reality it is situational! Although viable organisms may be present in a material, they would only be able to replicate if appropriate growth conditions were present. In terms of infectious disease, the term "virulence" is used to describe the ability of an organism to replicate in a susceptible host and cause infection. According to Zinsser's *Microbiology*, virulence is "a quantitative measure of the degree of pathogenicity of a particular microorganism. Virulence is usually measured by

the numbers of microorganisms necessary to kill or alter a particular organism under standardized test conditions" [7].

Not surprisingly, virulence has been and continues to be an area of very active research within the general study of host–parasite relationships. Virulence depends not only on the route of exposure and the number of organisms to which a host is exposed but also on the general health of the host organism studied. Virulence is far too complicated a subject to be covered in depth in a relatively brief chapter, but some general information can be introduced. Of the many thousands of species of microorganisms known, only about 300 have been reported to have the ability to produce disease [7]. It is staggering to think that there may be statistically more microbial species not yet known than those that are known and that there are by some estimates roughly $10^{30}$ viable microbiological cells present on earth at any given time. On the average human, there are roughly 10 bacterial cells per human cell, which means the risk of disease from microbial infection is remarkably low considering their ubiquity and astonishing diversity [8]. This, of course, means that the virulence of most environmental organisms is zero, and fortunately, among those that produce disease, virulence is, in the case of most pathogenic species, generally quite low as well. Readers may find this information surprising because in the pharmaceutical industry, the fear of microorganisms is such that there is a tendency to imagine that infectious disease is a distinct likelihood in the wake of any microbial contamination event.

Even among pathogenic organisms, which are those known to have some level of virulence in humans or animals, it can require a substantial contamination insult to result in a measurable pathological effect. Finlay and Falkow reported in *Microbiological Reviews* that inoculation of healthy volunteers intradermally with virulent bacteria could require as many as 5 to 10 million organisms to initiate an infection [9]. Even extremely virulent organisms such as *Francisella tularensis* may typically require more than 10 organisms capable of replicating to initiate infection. Studies on viruses have shown that typically several hundred to several thousand infectious virions (individual viruses) are required to initiate an infection; however, more recent studies indicate that around 20 Norovirus (genus *Calicivirus*) particles can initiate an infection [10].

A potentially pathogenic organism, even in a weakened host, faces a typically hostile, well-defended environment, and thus the barriers to initiation of infection are high. Thus, it is not surprising that, for example, the terrorist attacks with *Bacillus anthracis* (even though they involved millions of specially purified and weaponized spores designed to disseminate in the environment) produced very limited morbidity and mortality.

In no way do is this meant to imply that the data concerning microbial virulence mean that the health care industry in general or the pharmaceutical industry specifically can or should take a relaxed attitude toward the dangers of microbial contamination. Laxity with respect to contamination control is something that should be diligently avoided. Rather, it is possible and reasonable for industry and regulators to take a more scientific and hopefully more realistic approach to risk analysis and management regarding microbial contamination. Or to put it another

way, overreaction to microbiological risk and the resulting emphasis on absolute proof of contamination risk mitigation can introduce very significant cost increases with no real benefit to the end user of the product. In fact, in some circumstances, it can result in a quite safe product being rejected, which is wasteful and perhaps even dangerous to overall population health should the product be in short supply. The question should be what are realistic expectations for the production and dissemination of "sterile" health care products? Scientifically enlightened regulation would then not consume resources by focusing on comparatively low-risk elements in the product supply chain but rather on elements known to produce a greater risk of patient risk as measured by actual injury.

## 6.7 REGULATIONS AND ASEPTIC CONTAMINATION RATES

There is substantial ambiguity in the regulations concerning the ability of manufacturers to produce "sterile" products. For example, although one can find numerous suggestions in government regulations and guidelines that a target of zero contamination in media fills is appropriate, one cannot find any guideline or standard that completely rules out the likelihood of any single process simulation test containing positive units. Parenteral Drug Association (PDA) Technical Report No. 22, *Process Simulation Testing for Aseptically Filled Products*, states in the section on acceptance criteria and interpretation of results that:

> despite the number of units filled during a process simulation test or the number of positives allowed, the ultimate goal for the number of positives for any process simulation should be zero. A sterile product is, after all one that contains no viable organisms. There are, however, numerous technical problems in achieving this goal . . . thus, a limit of some low number other than zero is often chosen [11].

The PDA position on this point is realistic and scientifically defensible.

This statement and similar statements in other guidance documents, however, need further dissection if the full context of their meaning is to be grasped. There is an unfortunate assumption often made regarding media fill testing, which is that a zero result means that the ability of the process to make "sterile" product has been validated. There are two reasons why this assumption must never be made.

First, the sensitivity and limit of detection of media fill tests are impossible to establish. "Sensitivity" refers to the range of environmental organisms that could be grown on the media fill test media system. Put another way, this is the number of species that could be grown and recovered. This sensitivity data are really impossible to derive and are no doubt highly variable because they depend significantly on the condition of organisms in the environment. Many, if not most, organisms in the environment are nutritionally and chemically stressed to one degree or another, and by many estimates, the number of nonculturable organisms might exceed those that are actually culturable under some condition. Also, the limit of detection of the media fill test is quite a lot higher than zero. Fertility or growth promotion testing on

media fill test media uses inocula in the range of 10–100 CFU. Lower inoculum levels run the risk of negative growth results. Therefore, the limit of detection is greater than 0 even among organisms well adapted to grow in the soya bean casein digest broth typically used, and not all organisms likely to be in the environment will be grown and recovered by this medium.

Second, it is microbiologically incorrect to think that media fill tests can in any way demonstrate the complete absence of viable organisms; they can only show that there are not enough viable, nutritionally adapted organisms present to initiate growth on the chosen medium. As previously discussed, no bacteriologic media can recover viruses, and some viruses, as we all know, are important pathogens. Thus, the phrase "sterile media fill," which is a common linguistic construction in pharmaceutical industry, is really only true with clear and very significant qualifications. These qualifications are in fact so significant in nature that for scientific veracity, the term "sterile media fill" should never be used. It certainly is true that there were not enough cells in the environment that entered into each negative container to produce visible growth; however, this does not come at all close to proving the absolute that is "sterility" by any definition of that word.

It is reasonable at this point for readers to ask two questions:

1. Why don't we try to create media fill conditions more conducive to the recovery of any organism that might be present in the environment?
2. Why don't we require a growth promotion or fertility test outcome that shows growth at an inoculum much lower than 10 CFU and preferably at 1 CFU?

The answers in both cases are the same–because doing so is simply not possible. With a great deal of study, it might be possible to find a media that would recover a broader spectrum of organisms, but doing so would no doubt cause us to lose the ability to detect some organisms that are currently detected. Indeed, sometimes firms do conduct media fills using what are often called anaerobic media. (It should be noted true or "strict" anaerobic conditions are not a realistic possibility in an aseptic manufacturing facility.) Technically, anaerobic organisms do not require oxygen for growth; in fact, strict anaerobes do not tolerate the presence of any oxygen, meaning air is poisonous to them. Therefore, these anaerobes would be recovered only in highly reduced chemical conditions in which $O_2$ is quantitatively absent. So, strict anaerobic conditions are unlikely to exist in any production facility; what is far more likely to exist are conditions in which the presence of $O_2$ is significantly reduced. So, really what so-called anaerobic media fills do is bias the recovery toward organisms that prefer to grow at low $O_2$ levels, which are known to microbiologists as microaerophiles; they may also be known as facultative anaerobes or aerotolerant. Of course, conditions of growth media and incubation favoring these organisms will disfavor the growth of organisms requiring the presence of greater amounts of $O_2$. For this reason, the need for media fill tests done under reduced $O_2$ tension has always been a debatable point. Some industry authorities favor the idea, but others do not. What can be safely said is that neither standard media fills nor so-called

anaerobic tests will grow *everything*, but they will probably grow *different things*. Also, there will be a subset of environmental organisms adaptable enough to grow in both conditions. We must then conclude that the value of specific media fills done under so-called anaerobic conditions is limited because it seems reasonable to consider the media fill not as an absolute measure of anything but rather as a generalized evaluation of microbiological control conditions at a specific point in time.

The authors realize that what we have suggested in this section of the chapter is a significant reduction in the value many firms and some regulatory investigators place upon the media fill test. We are suggesting simply that there is a correct level of valuation or emphasis to be placed on the media fill. We have observed an increasing tendency to think of media fill tests as true validation events, which we believe is scientifically and statistically wrong. There has been a tendency to put the media fill test on a plane with biological challenges performed in the support of sterilization process validation, which is scientifically inappropriate. It is not possible to calculate a probability of nonsterility or SAL from a media fill test. Only a maximum contamination rate can be determined, and even then it must be considered that no test could recover all potential microbial contaminants. A legitimate claim for a media fill test with zero visible contamination is that an insufficient number of organisms capable of growth under the situational nutritional conditions were present and hence no growth was observed. We hope readers will agree that this falls well short of the claim of "sterile media fill" and certainly does not support a claim that a SAL can be derived from the number of units filled in any given test. It must then follow that it is also wrong to add the total number of media fill units on a given aseptic production line and then claim that the SAL is equal to that contamination rate value. Perhaps most importantly, it is a serious mistake to think that conducting any given intervention or series of interventions in multiple media fill tests and observing no growth means that these interventions are "validated."

The authors have proposed a risk analysis method regarding aseptic processing that we believe can be more accurate than a media fill in predicting microbial contamination potential [10,11]. This method, referred to as the Akers-Agalloco method, is beyond the scope of this chapter. However, some firms have used it successfully, and some evidence indicates that it can be predictive of weaknesses in contamination control [12]. Other aseptic processing risk evaluative methods may be effective and should, in our view, be considered as an adjunct to media fill testing. The limitations of microbiological analysis as a measure of the attribute of sterility have been poorly recognized in industry, although we believe this is slowly changing. The limitations of microbiological analysis are not limited to media fill testing but rather apply to such highly valued activities as environmental monitoring and sterility testing as well. A concept of acceptable commercial sterility or safety would be better applied to aseptic production than absolute sterility. The idea that we should expect every unit in an aseptically product lot to be sterile, when it is not scientifically possible to prove or even expect such an outcome, is wrong.

## 6.8 CONSIDERATIONS REGARDING ENVIRONMENTAL MONITORING

In the previous section, it was pointed out that current international regulatory guidelines allow that a media fill test might occasionally have a positive unit. In fact, under some circumstances in validation, a media fill with a single positive might not be disqualifying. This is a clear admission that at some level the authorities understand that "sterility" in aseptic processing is neither absolute nor a universally attainable outcome. Similarly, we know of no standard or guideline that suggests that an environment must be completely free of all detectable organisms at all times. Most guidelines, including those issued by the FDA and the European Medicines Agency, suggest that to pick one sample type, samples taken in ISO (International Organization for Standardization) 5 environments should show that airborne viable contamination averages less than one viable colony per cubic meter. Therefore, both media fill acceptance criteria and environmental monitoring acceptance criteria allow that some low level of recoverable microbial growth is likely to occur at least occasionally.

To summarize the key points covered so far, the following conclusions can be drawn:

- "Sterility" is an absolute concept, and the act of sterilization is one that renders all organisms present in or on a material incapable of reproducing.
- A material need not be "sterile" to be noninfectious, and the risk of infection from a small number of organisms is in most cases quite low.
- The number of species known to be capable of producing infectious disease is a very small subset of the constellation of known microorganisms.
- The existing standards and guidelines may suggest that aseptically produced products are "sterile," but there is realization, as found in the words of PDA's TR No. 22, that there are "numerous technical problems in achieving this goal." In fact, careful reading of the standards and guidelines confirms that they allow for nonsterile environments and imperfect media fill results.

We are then brought face to face with a central problem in aseptic processing. If we cannot truly prove that "aseptic" products are "sterile," and, in fact, our standards recognize that contamination in process simulation testing and environmental sampling is likely, why do we persist in calling these products "sterile?" A further exploration of the concept of asepsis is required to adequately consider this question.

As previously mentioned, it appears that much of the pharmaceutical industry and governing competent regulatory authorities considers "aseptic" and "sterile" to be more or less synonymous. However, in academic science, as reflected in common technical usage, it is clear that in the science of microbiology, "sterility" and "asepsis" have never had the same technical meaning.

The word "sepsis" is derived from the Greek verb meaning "to decay or to rot." The prefix "a" means "without." Therefore, in the purest sense, the word "asepsis"

means "the elimination of decay." In the medical sense, the word "sepsis" has come to mean something very close to infectious. The Jawetz *Medical Microbiology* text defines condition of sepsis or septic as "the presence of pathogenic microbes in living tissue" [4]. It follows then that "aseptic" is defined as "the absence of *pathogenic* microbes." Thus, in the clearest technical sense, an "aseptic" product is certainly safe because it lacks infectivity, but it may not be "sterile" in the absolute sense of that term [6]. So, if products produced in industrial aseptic processing were indeed infectious and therefore routinely contained organisms capable of producing infection, we should expect significant morbidity and perhaps even some mortality associated with this subset of "sterile" products. However, there is no evidence that there are any significant risk associated with industrial aseptic processing conducted in compliance with standards that have been promulgated in the past two decades.

The authors suggest that PDA dealt with this contentious issue in a scientifically honest manner in the current version of that association's Technical Report No. 22 [10]. Perhaps PDA's statement has gotten little notice because it is found in "Appendix 2—Definitions" rather than the main body of the technical report. PDA defines "sterility" as "free of viable organisms;" however, below the definition is a note that says "in practice, no such absolute statement regarding the absence of microorganisms can be proven." However, we believe that many thoughtful readers would hasten to point out that scientific evidence and the opinion of PDA regarding the provability of "sterility" in aseptic processing matters very little if the regulatory authorities hold industry to a standard of absolute sterility [1]. In a practical sense, we would have to agree with that observation, although we are required to point out again that there is no current standard in force that appears to consider "sterility" in cleanrooms possible, even using the technically limited measure of environmental recovery and subsequent growth of contamination [13,14]. We point out again that it is not appropriate to consider a zero outcome to be the equivalent of "sterile." We cannot prove a negative absolute, so we must reiterate that zero does not mean "sterile"; it only means that on the occasion of this test or sample, no organisms that would grow to a point where they could be detected by inspection were present.

It is not appropriate to simply state that contamination in aseptic processing areas is a fact of life; in the interest of scientific balance, we should look at the technical literature with regard to the effects of human occupancy on cleanrooms. First, we should examine the level of skin contamination present on humans. Data published in Ljungqvist and Reinmüller's *Ventilation and Airborne Contamination in Cleanrooms* indicates that the total population of aerobic bacteria on human skin is typically greater than 1.2 million/$m^2$ in the head and neck regions of both male and female subjects [15]. The numbers of organisms present on the hands and arms is typically in the range of 0.9 to 3 million/$m^2$ on healthy subjects. A number of studies have been done on the release of total particulates by humans in cleanroom clothing [16,17]. In the same publication referenced above, a study conducted by Takasago Thermal Engineering found that a fully gowned person sitting in a cleanroom would release about 15,000 particles per minute. A walking individual, according to this study, releases roughly 157,000 total particulates per minute. In a study published by Reinmüller in 2001, it was reported that the typical ratio between total particles

larger than 0.5 μm and viable aerobic organisms recovered is in the range of 600 to 7000 to one [15]. Studies done on personnel clothed in new full coverage cleanroom gowns found that these people release 600 to 1300 total particulates per hour in the larger than 0.5-μm size range and that among these were as many as 40 CFU of viable aerobic organisms. These data are generally consistent with the findings published by Dr. William Whyte [13]. Reinmüller's data also showed that as the gowns aged and were subjected to washing and resterilization, both the number of total particulate and the level of microbial contamination increased. Not surprisingly, these studies indicate that there is also a correlation between the amount of physical activity undertaken by personnel as a source of contamination, or put another way, the amount of contamination they contribute to their surrounding environment. Reinmüller also reported that microbial contamination is strongly associated with particulates in the 0.5-μm size class. It has been widely assumed that microorganisms in aseptic processing areas are associated with particulates in the 5- to 10-μm size range, and possibly the emphasis placed on particulates in this size class in some regulatory recommendations is an upshot of this assumption. However, there appears to be little factual basis for an emphasis on 5-μm particulates, and given the low frequency at which particles in this size range are recovered, there seems little justification for using them in a classification exercise because the counting statistics are poor.

From the work of Whyte, Reinmüller, and others, it can be estimated conservatively that a typical, properly gowned cleanroom worker will contribute 10 to 100 CFU of viable aerobic organisms to the environment per hour [13,14,15,16]. It is obvious then, given the high air exchange (which results in correspondingly high contaminant dilution rates) used in today's ISO 5 cleanrooms, that the total recovered microbial concentration should be very low. However, these data also clearly indicate that even the best cleanrooms do not under any circumstance approach "sterility." In fact, it could be argued that they can only attain asepsis if we are fortunate enough to have facilities staffed only by personnel who do not release pathogens, a circumstance that is quite beyond our ability to prove.

Let us relate these experimental data to a frequently discussed and quite current regulatory issue. It has recently been suggested in regulatory findings that firms should test their most critical process equipment for the presence of microorganisms and take action against product if viable organisms are recovered on samples taken from a production operation. Because operators must in many aseptic operations physically assemble production equipment such as filling pumps and needles and because people release microorganisms during work in cleanrooms, it clearly should not be considered unreasonable to recover low-level contamination in and around areas where people work. In fact, given the variability associated with the sample and recovery methods and what we know of their sensitivity, the expectation is that some relatively low frequency of contamination would be observed.

The stopper bowl is frequently cited as a critical surface that must be tested, and it was been suggested that contamination found on this surface is indicative of a loss of sterility assurance. However, because the recharging of stopper feed hoppers is typically a manual operation, it seems unreasonable to believe that the occasional

recovery of organisms should be considered indicative of a loss of control. We are unaware of any research done on gowned cleanroom employees that indicates they do not consistently shed viable organisms. In fact, from the data published in refereed journals, it appears that release of organisms by personnel is not only inevitable but also completely normal. Therefore, to suggest that remedial action must always follow the recovery of organisms at any location in a cleanroom is wrong. It would also follow that requiring investigations to be done whenever an isolate is recovered in an ISO 5 room will only create busy work rather than enhance process control. Investigations into circumstances that are expected and normal are of no real operational value.

It is clear given the research and empirical data that a low but random level of recovery is completely normal in manned aseptic processing and therefore noteworthy only if there is a significant change in level or incidence rate. Scientific thoroughness requires us to consider than in almost every case, environmental monitoring is conducted by a gowned member of the staff and that this sampling activity is also prone to some level of adventitious contamination in the same manner as it might be derived from production personnel.

So, it is unreasonable to think that the discovery of organisms that one should expect to be present in low numbers represents a loss of sterility assurance. It is scientifically and statistically more appropriate for industry standards and regulations to recognize that "sterility" cannot be assured in any cleanroom under normal operational circumstances. This is true even if we define "sterility" as merely the absence of viable organisms, which is a very liberal definition of the word. Operations that carefully and scrupulously comply with the letter and spirit of current Good Manufacturing Processes (cGMPs) cannot be expected to yield uniformly "no growth" results, which clearly means that some recovery of viable organisms in any human-scale cleanroom is in fact *normal*. As long as people are present, they are the most likely source of microbial contamination, and because there is nothing they can realistically do to completely eliminate microbial and particulate shedding, it follows that no exceptional assignable cause can be identified in an investigation.

Because the presence of personnel in the environment always ensures that contamination will be present, it can be argued that it is the total absence of contamination that would reflect an exceptional condition! Certainly, it is expected that the recovery of viable organisms from critical ISO 5 or EU grade A environments should be observed at a very low rate. However, that very low rate will always be greater than zero, which implies that a background level of contamination is present, which—not surprisingly—our intensive monitoring efforts sometimes recover.

## 6.9 PRACTICAL CONSIDERATIONS IN CURRENT GOOD MANUFACTURING PROCESSES–COMPLIANT ASEPTIC PROCESSING: ACHIEVING STERILITY BY DESIGN [17]

The scientific considerations regarding aseptic processing covered to this point in this chapter can help readers better understand the difficulties associated with the

manufacturing of sterile products using aseptic technologies. In practice, however, regardless of the regulatory expectations or the technical challenges resulting from a given product, the fact remains that at its basis, aseptic processing is quite simply nothing more than the control of contamination at a very high level. Provided an aseptic processing achieves that objective, product safety, which is the most critical attribute associated with an aseptically produced product, is assured. As can be seen from the research done in the area of aseptic processing already discussed in this chapter, in principle, high-level contamination control is primarily a function of how well a process manages risks associated with human contamination.

The authors have coined the term "sterility by design" (SbD) to underscore an aseptic production focus on facility design, process design, process control, and operational effectiveness that results in the reduction of personnel interaction with sterile materials. There is no more effective way to achieve high performance regarding contamination control (and hence risk management) in aseptic processing than optimal management of risk arising from human workers. By far the best approach to aseptic processing is the complete elimination of contact between human operators and the area in which aseptic processing is accomplished. This eliminates all contact among personnel, sterile components, and product, and it obviates all direct participation by operations in the aseptic setup, fill, and seal phases of manufacturing. This aseptic processing ideal has been released and will likely become the norm during the careers of most of the readers of this text.

At the present, however, manned cleanrooms, or aseptic processes with some degree of direct human intervention requirement, are typical. The concepts of SbD have three simple fundamental performance objectives:

1. To ensure separation between human operators and the most risk-intensive locations in aseptic processing to the greatest extent possible
2. To limit personnel interaction with sterile materials at all times and ensure that when such contact is unavoidable, it occurs only under conditions that are most favorable to the reduction of contamination risk
3. To the greatest extent possible, reduce the presence of personnel in the critical aseptic environments

The following are key SbD considerations, which can be used to form the basis for the identification of critical process design considerations, validation features, and critical control points:

1. Product considerations
   - The product must be compounded and sterilized using validated methods that both ensure sterility and the conservation of the product's chemical or biological therapeutic attributes.
   - Physical sterilization using heat or ionizing radiation is generally straightforward and low in risk.
   - Sterilization of products by filtration is highly reliable but more risk intensive than physical sterilization processes.

- Control of bioburden before sterilizing filtration is critical because it can ensure that the filter is used within its defined use conditions and that microbial toxins are avoided. *Under no circumstances is the presence of conditions that favor microbial proliferation in the product acceptable because the proliferation of contaminants is universally objectionable*.
- Active ingredients, excipients, and all product components should be packaged in ways that allow surface decontamination of their containers. When product is supplied to the critical zone in sterile containers (e.g., sterile powders, sterile components, or subunits), it should be introduced in a manner that retains at least one hermetic layer until entry into the ISO 5 critical zone.
- Product contact materials that enter aseptic environments should always be sterilized using a validated process.
- Product supply and connection should be made within the ISO 5 critical zone.

2. Containers and closures
   - Containers and closures must be cleaned, prepared (e.g., lubricated), and sterilized and depyrogenated using validated processes.
   - Containers and closures should be introduced in a manner that retains at least one hermetically sealed layer until entry into the ISO 5 critical zone.
   - Containers and closures should be selected and specified for reliability of handling in the processing equipment because operator interventions are frequently required as a result of poor component feeding and handling.
   - Containers and closures should be of suitable quality for their intended use. Higher Acceptance Quality Levels (AQL) for defects can result in a reduction in the need for corrective interventions.
   - Containers and closures bulk containers should be designed for ease of opening and minimization and isolation of operator activity. Inventories of these materials within the aseptic environment should be minimized.
3. Facilities
   - Facilities should be designed for ease of cleaning and sanitization and decontamination.
   - The facility should be designed to minimize the potential for transfer of contamination into the aseptic processing area from surrounding environments.
   - The aseptic processing area should be maintained at a positive pressure to prevent the airborne ingress of contamination from less clean environments.
   - An air pressure differential cascade should be established in which lower classified environments are balanced so as to remain negative to higher classified environments (e.g., ISO 5 > ISO 6).
   - HEPA-filtered air should be supplied through all classified areas, and HEPA filters should be subjected to annual or semiannual efficiency testing.

- Differential pressures between areas should be continuously monitored and alarmed.
- Temperature and humidity established to maximize personnel comfort during operations, humidity should be approximately 50% or less, and temperatures should obviate any possibility of operator discomfort or perspiration.
- Interlocks should be used to prevent inadvertent pressure reversal.
- Closed RABs and isolators should be the preferred processing environments.
- Facility surfaces should be resistant to the action of cleaning, sanitizing, and decontamination chemicals.
- The aseptic facility should be maintained in "clean" operational state at all times and periodically sanitized or decontaminated. Isolators and closed RABs should be decontaminated with sporicidal agents at regularly scheduled and validated intervals.
- A "just-in-time" approach to material management should be observed in all aseptic areas to the greatest extent possible.
- Smoke studies, expectations for unidirectional air flow, absence of eddies, and other subjective expectations imposed on HVAC systems should be recognized as nondefinitive means for assessing environmental performance.
- In facility design, air exchange rates (air changes per hour) are the preferred indicator of the contamination control capacity of the environment.

4. Equipment
   - Product contact surfaces should be sterilized by validated methods. (Vibratory feed systems may be exempted from this requirement provided they are high-level decontaminated with a sporicidal agent in situ as is typical in isolator or closed RABs systems.)
   - Sterilization-in-place and clean-in-place procedures should be used whenever possible; these methods are always superior to aseptic assembly from a contamination control perspective.
   - Equipment that cannot be sterilized in place should be fully assembled before sterilization to reduce the need for aseptic assembly.
   - Equipment and utensils should be sterilized in sealed containers whenever possible. When they must be sterilized as wrapped articles, the wrapping must be tear and puncture resistant and impervious to moisture.
   - Equipment and utensils should be introduced in a manner that retains at least one hermetically sealed layer until entry into the ISO 5 critical zone.
   - Equipment and utensils should be sterilized and depyrogenated using a just-in-time approach.
   - Equipment should be selected for high reliability, ease of change over, and adjustment; equipment that can be set up with minimum manual intervention results in superior contamination risk management.

- Remote adjustment of equipment operational parameters should be used whenever possible to further reduce contamination risk from intervention.
- Tool-free change over from one format to another should be used when possible.
- Equipment should be tolerant of minor deviations in component specification and should be easy to keep in proper alignment.
- Containers should be handled and positioned positively rather than passively to avoid corrective interventions as a result of jams, tip-overs, or misfeeds.
- Equipment (and to some extent critical facility systems) should use feedback systems for ease of control, operation, and documentation.
- Nonproduct contact portions of the equipment should be easily decontaminated and should be designed to preserve the integrity of the ISO 5 critical zone.
- All equipment surfaces should be resistant to the potential corrosive action of sanitizing and decontamination chemicals as well as cleaning agents.

5. Procedures
   - Procedures should be critically reviewed to emphasize the need to reduce the numbers of interventions of all types and to simplify all aseptic processes to the greatest extent possible.
   - Interventions should be designed to ensure minimal risk of contaminating sterile materials.
   - All interventions performed during aseptic processing must be recognized as increasing the risk of contamination dissemination.
   - All interventions should be performed using sterilized tools.
   - Intervention procedures should be established in detail for all inherent interventions and more broadly for corrective interventions.
6. Personnel
   - Personnel must receive initial and periodic formal training regarding CGMP, aseptic processing, general contamination control science, aseptic gowning, and job-specific tasks.
   - When appropriate, personnel should be initially qualified and periodically assessed for their proficiency in aseptic gowning.
   - Personnel should be trained and then initially qualified and periodically assessed for proficiency in aseptic technique.
   - Personnel should be disciplined and detail oriented so they may conform to the highest standards of aseptic technique at all times.
   - Personnel should be monitored upon each exit from the aseptic core. (Gloves inside aseptic enclosures should be monitored at the end of the batch or campaign.)
   - Gown materials should be cleaned and sterilized using validated methods. A fresh sterile gown should be used by the operator on each entry into the aseptic environment.

- Gloves on aseptic enclosures should be replaced periodically, sterilized, and integrity tested.
- Manual filling by aseptically gowned personnel should be recognized as an anachronistic throwback to an earlier time and no longer used for aseptic processing.

7. Monitoring
   - Overreliance on monitoring of the environment is a common mistake; it is important to consider that it is impossible to monitor quality into a process or product.
   - Environmental monitoring activities are human interventions and must be treated as such.
   - Monitoring of operational facility and equipment parameters in all stages of aseptic processing is very important, and when advanced aseptic technologies such as isolators or closed RABs are used, is generally more important than environmental monitoring.
   - It is critical to avoid a false sense of security taken from the review of environmental microbiological data and media fill test results; one must be aware of the fact that in microbiology zero does not mean "sterile." Rather, it means nothing detected.
   - Avoid overconfidence from environmental monitoring data and always rely on physical data and careful expert supervisory oversight to ensure operational integrity in aseptic processing.

Attention to these rather simple concepts in sterility by design will ensure a design space optimized for the manufacture of safe and well-controlled sterile product. This will in parallel ensure an aseptic processing culture that is both reliable and compliant at all times.

## 6.10 THE NEED FOR SCIENTIFICALLY VALID STANDARDS AND REGULATIONS

We hope that after reviewing the concepts of "sterility" and "asepsis" that it can be agreed that achieving either of these goals in cleanroom product manufacturing is impossible to ensure, much less to prove, at the current state of technology. We do not object to the label "aseptic processing" for the production of product of high microbiological purity in cleanrooms. However, we should all understand that the actual demonstration of "asepsis" in each and every unit of product is not possible and that it is equally impossible to demonstrate that some general condition called "sterile" exists. It is inappropriate scientifically to consider that a cleanroom with aseptically gowned personnel could be "sterile." A "sterile" cleanroom would require "sterile" human operators using perfect contamination-preventing clothing while working in a "sterile" environment, and these conditions cannot presently be attained.

Because these environments are not "sterile" and because humans release organisms at various rates depending on movement and gowning effectiveness, we should not be surprised at the periodic random discovery of some viable organisms in even the most critical locations within a cleanroom. We cannot agree with the notion that organisms found on two closely spaced days on a single site in a cleanroom are indicative of an adverse trend. We believe that this contention is statistically unreasonable because workers will release organisms continuously, albeit at varying rates per unit time. With that in mind and considering the fact that the samples themselves are taken by other humans who also continuously release organisms, how can low-level contamination legitimately be considered a trend even if seen 2 or 3 days in a row? Also, how can one consider the occasional positive result in a media fill test as anything but the natural consequence of the environmental conditions under which the study is conducted?

Upon careful analysis, we suggest that the aseptic processing industry has fallen prey to the inappropriate application of absolutist thinking totally unsupported by scientific fact. We believe that in the context of aseptic processing, we are applying the absolute meaning of the word "sterile" in a wholly inappropriate and ultimately self-defeating manner. There are well-meaning industry practices and regulatory compliance expectations that may lead to an unfortunate use of material and human resources. Among them are:

1. The imposition of expanded environmental monitoring schemes because it is erroneously thought that as contamination is reduced more testing is required to detect lower microbial levels as cleanroom facilities improve and advanced aseptic processing systems such as isolators and close restricted assess barriers are used.
2. The imposition of zero microbial contamination as a fixed requirement at any location in a cleanroom, including on so-called "product contact surfaces."
3. The suggestion that the recovery of any mold at all in a cleanroom is indicative of a loss of control. Mold should be infrequently observed, but it must be realized that it is ubiquitous in nature and can be found as a passenger on human skin, hair, and clothing. Certainly, cleanrooms should not be colonized by mold, but this is a different matter from the rare random recovery of mold.
4. The linkage of product release to environmental monitoring data. If we are to reject product for random low-level background contamination in manned cleanrooms, we are merely adding to the cost of production with no commensurate benefit in patient safety.
5. The dramatic increase in personnel monitoring and testing in terms of both frequency and location on personnel.
6. The suggestion that any contamination found in a media fill test is indicative of a loss of process control.
7. The suggestion that the cooling zone of depyrogenation tunnels should be sterilized in the complete absence of real data indicating that a risk exists.

It should also be recognized that the term "sterility assurance level" in the context of aseptic processing has no scientific merit and has been unfortunately but understandably misapplied in efforts to correlate what are really media fill contamination rates to the label claim of "sterility." We should also recognize that many of the numerical standards that are in use for testing and monitoring of aseptically filled products were not scientifically derived and have never taken the analytical methods sensitivity into a account. Additionally, many standards and expectations were implemented without the benefit of careful and critical peer review. Scientific honesty also requires that we admit that the methods used to evaluate the microbial content of the environment vary tremendously with respect to the results they yield as studies by a number of scientists have already shown.

## 6.11 AN OVERVIEW OF STERILIZATION AND DECONTAMINATION

Sterilization is, as already mentioned, a very different thing from aseptic processing, although obviously, the product pathway and product contact parts are sterilized before use in aseptic processing. Thus, sterilization is required in all sterile product manufacturing activities. In this section of the chapter, we are referring only to sterilization processes that actively destroy microorganisms. To be clear, this means only methods that physically sterilize using, for example, heat, energy from radiation, or chemicals.

Again, we must begin with definitions. As a noted authority on the subject of sterilization and decontamination, Dr. S.S. Block, wrote in the definitions chapter of his widely referenced book titled *Disinfection, Sterilization and Preservation*: "Definitions are man-made; they do not come to us from on high" [18]. He goes on to write:

> Death is not exact. When is a person dead? When is he no longer breathing? When he is brain dead? When all the cells in his body are dead? When is a product sterile? When all life in it has been killed or when it has been heated at X temperature for Y minutes or is it when its microbial population (bioburden) has been reduced by z D values? It is what we say it is according to the way we construct our definition.

In the case of sterilization processes in the health care industry, we say sterilization begins is at a probability of nonsterility (PNSU) of 1 unit in a million. The way in which this definition, often given as a "SAL of $10^{-6}$," is used in our industry, it is almost as though it is an immutable law of science. We often forget that the selection of this value as a target or specification was more or less arbitrary. As Dr. Block put it, that is the way we have constructed our particular industry specific definition. We could have chosen another value, but we didn't; we chose this one.

There are various historical perspectives that have been advanced regarding the choice of a PNSU of not more than 1 unit in a million. Some have written that perhaps we borrowed this value from the NASA program for the sterilization of spacecraft.

Perhaps it evolved out of a general understanding in the medical community that it is a suitable risk value for parenteral products that could be sterilized in their containers. Whatever its actual genesis might have been, what is clear is that those who chose this value understood clearly that they were not defining a technical limit for the condition of "sterility." Rather, they were defining an acceptable level of risk, which is clearly quite a different thing altogether.

We often hear people speak as though the SAL or more precisely PNSU of $10^{-6}$ is an attribute that all terminally sterilized products have. This if, of course, untrue because $10^{-6}$ is not a process capability; rather, it is a minimum acceptable level of performance. Also, the sterilization of components or other production-required equipment and materials always results in SALs well in excess of $10^{-6}$. In fact, the failure to understand how low the true risk associated with well-designed and validated sterilization processes really is quite often results in extremely excessive margins of safety being arbitrarily built in to cycles.

So if someone says that an aseptically produced product has a SAL of at least $10^{-3}$, the reader should now know that this is a meaningless statement because we have no means of tabulating a SAL or PNSU for an aseptically produced project. In the case of terminal sterilization, we can demonstrate quantitatively that we have met or exceeded the established minimal risk value for sterility, which is a SAL or PNSU of $10^{-6}$. Do not fall into the trap of thinking that this means physical sterilization is, as often heard, "three logs better" than aseptic processing; this is not at all the case. As already noted, any attempted direct quantitative risk comparison between physical sterilization and exclusionary methods such as aseptic processing is doomed to fail because they operate in entirely different ways such that there is no scientifically valid means of initiating a comparison.

A noted regulatory investigator, Mr. John Sharp, once said (we suspect partly in jest) that "sterilization probability of one in a million is fine if you are not the millionth bloke" [19]. However, in the case of physical sterilization, the way in which we sterilize our materials; components; and in many cases, final products means that the probability of any user of those products being affected by a correctly run sterilization process is so close to zero as to be no cause for technical debate at all. In our combined seven decades of experience in microbiology and sterilization processes, we have actually never seen a process that yielded a minimal PNSU of exactly $10^{-6}$. This is because all of them provide substantially less risk of a nonsterile event than that, and most of them deliver actual lethality values far in excess of the minimum. The purpose of any sterilization process is the elimination of bioburden; however, the mechanisms used for development and validations of these processes rely on the use of very highly resistant biological indicators. These biological indicators are not only as much as 1 million times more resistant than typical bioburden; they are also challenge the system at enormously higher population numbers than could be present in any normal environment. A common misunderstanding is that the destruction of $10^6$ spores on a biological indicator equates to a PNSU of $10^{-6}$. Actually, the complete kill of, for example, a moist heat biological indicator inoculated with *Geobacillus stearothermophilus* spores at a population of $10^6$ ensures a PNSU substantially lower (better) than $10^{-6}$.

So, an important fact to remember is that when physical sterilization is done with any degree of competence, it is so reliable and so well quantified that it is a truly insignificant risk modality. This does not mean that developing and validating sterilization processes is easy, but it does mean the technologies, whether they are heat, chemical, or radiation, are well understood and comparatively easy to quantify. The result is that we do not see sterilization cycles in terminal sterilization or materials sterilization in which there is the slightest risk of injury even if the entire population of the planet was administered the product. In fact, even this criterion is often exceeded by tens, if not hundreds, of orders of magnitude. Readers are urged to not only delve further into published technical literature but to also spend some time with a calculator or computer investigating the true risk of a nonsterile unit at the lethality levels afforded by the typical industry autoclave cycle.

## 6.12 MICROBIAL DEATH CURVES

The death of microorganisms, when subjected to lethal treatments regardless of sterilization method, follows a fairly close approximation of first-order kinetics. What this means is that when the death curve, which indicates the destruction of microbial population per unit time, is plotted on semilogarithmic graph paper, something close to a straight line results. When subjected to linear regression analysis, the result should be a fit that confirms reasonable linearity. What this essentially means is that the slope is consistent over time, which is consistent with microbial death or kill, being the result of a uniform effect that has only minor variability in reaction time.

In practice, one will normally see a very close fit to the first-order kinetics with heat sterilization, whether it is dry heat or moist heat, and other forms of sterilization such as chemical and radiation. Under ideal chemical reaction conditions, broadly lethal sporicidal agents should also produce a close approximation of first-order kinetics. When nonlinear death curves are observed, quite often a latent or lag period is observed followed by a more characteristic linear curve. This latency is believed to be the result of manner in which the suspension culture of microorganisms interacts with the material onto which they were inoculated. In some cases, they form clumps of organisms in a matrix of inorganic salts and organic materials that result in the appearance of a type of protective biofilm that is difficult to penetrate.

This phenomenon probably plays a significant role in the observation of the so-called *substrate effect* in which the kill rate of an organisms appears to depend to one degree or another on the substrate upon which it was inoculated. Substrate effects may also related to hydrophobicity because moisture is often required to produce optimal spore kill rates. Bacterial spores, because of their extreme resistance to environmental stress in the form of heat, and chemicals are often used in the evaluation of sterilization processes, and the absence of moisture may reduce kill efficacy.

The effect of moisture can be seen quite clearly from the simple fact that it is necessary to run dry heat processes at far higher temperatures than moist heat

processes to achieve the same result. In 1933, Barker reported that moisture was essential to the denaturation and coagulation of proteins in moist heat sterilization [20]. Lewith reported similar findings; thus, it appears that moist heat kills by a different mechanism than dry heat, which is probably largely an oxidative process [21]. Wang et al. showed experimentally that activation energy and entropy changes for killing of spores and denaturing of protein are quite similar, which further supports the concept suggested by Barker [22]. It was further demonstrated in these studies and others that spores are quite permeable and freely exchange water with the environment.

Dry heat sterilization, because water vapor is absent, results in low water activity of the spores. Stated another way, dry heat sterilization occurs at low relative humidity. Dry heat sterilization is performed at a water activity ($A_w$) of zero (0), which is a relative humidity (RH) of 0%. In steam sterilization, the conditions are an $A_w$ of 1 and RH of 100%. Angelotti et al. showed that spore resistance actually increased from an $A_w$ of 0 to 0.3 [23]. They reported that spore kill rate increases of up to 100-fold were possible at reduced moisture levels. These data help explain the criticality of air removal, a factor often emphasized in moist heat sterilization. Because cold air and hot steam do not mix easily, insufficient air removal can result in low moisture, low temperature, and consequently poor kill at the sterilization target. Young points out that "all the air does not need to be removed from a sterilizer, but all surfaces requiring sterilization must be exposed to adequate moisture" [24]. This is further reinforced by the fact that in some moist heat processes, materials air is purposely left in the chamber to minimize pressure gradients across products being sterilized. However, provided that the air–steam mixture is adequately uniform, something that can be assisted by a circulating fan or water circulation, consistent sterilization is observed.

Moisture is not a factor only in heat sterilization; many sporicides are formulated in an aqueous base, and their effectiveness owes no doubt in part to the ability of water to permeate spores freely. It should be noted that moisture has been observed to be critical to the efficacy of gas sterilization by chemicals such as ethylene oxide, ozone, and chlorine dioxide.

## 6.13 TOWARD A MEASURE OF REAL PRODUCT SAFETY

It is increasing clear that what is needed in industry are real measures of regulatory compliance based on scientific and engineering fact rather than compliance based on supposition or tradition rather than science. In no area of compliance is the need for science- and risk-based regulation more critical than in the area of aseptic processing. The absolute nature of "sterility" as a concept has led to the evolution of compliance expectations that are, in some cases, both unscientific and unreasonable.

It makes no sense to set standards that cannot reasonably be attained. Doing so will do nothing but result in claims that sterility assurance is somehow lost when actually a cleanroom is being operated using current best practices and the contamination rate is at the established background level.

If we fail to base aseptic processing requirements on what is attainable rather than some scientifically excessive theoretical consideration of "sterility," we will do nothing but waste resources and product while at the same time failing to increase product safety. It may seem like we are doing something to improve product by appearing to tighten the standards, but in reality, unattainable standards will do nothing to improve real compliance or real product quality. Rather, they will simply require what can best be described as work without real tangible benefit.

It is understandable that many people involved in standard setting and regulatory policy would attempt to impose a standard of absolute safety because this appears to be the ultimate in assurance of safety. However, we simply lack the ability to operate cleanrooms in a "sterile" fashion, and none of our test methods can ensure that the attribute of "sterility" has been attained. The so-called "sterility test" is least capable of all.

The test for sterility has been applied to preparations for many years. In fact, tests for absence of viable organisms have been used in microbiology since the 19th century when the ability to culture and grow microorganisms in a laboratory setting was developed. The sterility test has been included in the USP for many decades, and the introduction of membrane filtration brought about broader applications of this growth and recovery methodology in the 1950s and 1960s.

However, in retrospect, the naming of the "absence of recovered viable organisms" test as a "sterility test" was an unfortunate occurrence.

From a purely scientific perspective, the "sterility test" cannot confirm the condition of "sterility" for three very good scientific reasons. First, we do not know what the actual sensitivity and limit of detection of the "sterility test" really is. It is reasonable to assume, however, that it is not zero, even among organisms that could possible be cultured with the media stipulated in the test instructions. Second, because we use a test that uses only two media intended to grow a broad spectrum of bacteria and mold, we know that it will not recover more fastidious organisms or important pathogens such as viruses that are obligate intracellular parasites and will not grow in culture media such as trypticase soya broth or fluid thioglycollate. Finally, because the "sterility test" is a sample depending test and the sample size is quite small given typical lot sizes, the statistical reliability of the test is severely limited.

Thus, the term "sterility test" is and always has been a misnomer in many respects. The test, if the result is positive, certainly shows that a lot of material is surely nonsterile. However, as is the case with any "zero" growth result in microbiology zero cannot correctly be interpreted as equivalent to "sterile." Actually, "no growth" only means that no growth was observed in this sample under the conditions of the defined "sterility test." What this means is that the "sterility test" is a test for the presence of detectable contamination in a limited sample population rather than a test for sterility. It also means that it is really a "sentinel" test from which it is presumed that the absence of organisms that could grow in the media and incubation conditions defined in the test, meaning that a sufficient level of microbiological safety is likely. We emphasize again, however, that we do not at this point have a true "sterility test."

Requiring industry to attain and confirm "sterility" is not the same thing as achieving that condition. We can only achieve what is possible; we cannot and should not be expected to conform to some theoretical ideal.

## 6.14 A FEW SCIENTIFICALLY MODEST PROPOSALS

1. Ensure that microbiologists or engineers who fully understand the underlying microbiological principles write all standards on microbiological quality. Microbiologists should not write chemical or pharmacologic standards, and it seems both pragmatic and reasonable that chemists and pharmacologists ought to leave microbiology to microbiologists.
2. Improve dialogue between industry regulatory inspectors and reviewers on the science of aseptic processing and the tools we use for aseptic process control.
3. Base decisions on process control and performance requirements for aseptic processing on measurable safety rather than theoretical or abstract requirements such as "sterility." The need to change validation requirements or process control requirements should be based on a real need to improve safety rather than on the perception that a closer approach to an absolute ideal is required. Thus, standards would be based on quantitative safety data rather than subjective opinion.
4. Ensure that numerical standards as they apply to microbiological control take full consideration of the limits of detection, accuracy, and precision of the methods. All too often, microbiological methods are assumed to be far more accurate and reproducible than they actually are. The difference between 5 CFU and 15 CFU may seem very significant to a chemist, but in microbiology, such differences can easily be the result of the method, the conditions of the organisms, or both. The arithmetic difference between $5 \times 10^5$ and $1 \times 10^6$ would be huge in a chemical assay; however, in microbiological serial dilutions, it is barely significant.

It seems reasonable to assert that those in the sterile health care product manufacturing field have to work to higher standards than food scientists, who only have to achieve "industrial sterility" in aseptic food processing. Actually, there is no real difference between "commercial sterility" in the food industry and the "sterility assurance" of our pharmaceutical processes; both terms correctly reflect the fact that these processes are not capable of "sterility" in the strictest scientific meaning of that word. However, as an industry, we must take care that our evolving attitudes and expectations regarding perfection do not blind us to reality or that we allow perfection as reflected in expectations to become the enemy of good (or better).

It is critical to note that none of the foregoing discussion is meant to suggest that we should relax our expectations that products manufactured aseptically and labeled "sterile" be made under stringent process control and uniformly diligent attention to detail. There is ample evidence that our industry has a rigorous commitment to ensuring that our "aseptic" processes are as good as they can be. So much are our "hearts in the right spot" that because of a misunderstanding of scientific principles,

expectations are established that are higher than is technically achievable. We believe it is reasonable to state that based on in-use safety data that products manufactured in compliance with current industry practices are safe.

The authors call the reader's attention to the PDA's *White Paper on Aseptic Processing* published in 1988 [25]. In our experience, products manufactured today using the approach described in that document would still be microbiologically safe. In fact, the case can be made that in the present day, the real danger to patients from sterile products is at the level of admixture in the pharmacy and administration.

It was reported by the World Health Organization (WHO) [26] that of each 100 hospitalized patients in the developed world seven will develop at least one healthcare associated infection. The rate of hospital acquired infections on the developing world is considerably higher with 10 patients out of each 100 admitted having at least one healthcare associated infection. These infections are not the result of contaminated product but rather result from treatment including parenteral injection. The same WHO report states that in high income countries, up to 30% of intensive care unit (ICU) patients are affected by at least one ICU acquired infection. The WHO further states that the costs associated with these infections are about $10 billion in Europe and $6.5 billion in the United States, and also asserts that most of these infections could be prevented by simple and relatively inexpensive measures such as improvement hand hygiene. These are real consumer safety issues to which industry, health care providers, and the regulatory community should focus their collective energy. Humankind will be better served if we were to devote our efforts to solving these problems rather than devoting unreasonable levels of resources to areas in the delivery chain where risk is already low.

Certainly, when organizations are found that are making product under conditions that do not comply with the cGMPs that exist in this industry for aseptic processing, aggressive enforcement action should always be taken. However, this does not mean that the vast majority of current practices are inadequate. Nothing is accomplished by punishing everyone for the sins of a few. In recent years, too many regulatory initiatives appear to be solutions in search of a problem.

Will we ever achieve demonstrable "sterility" in human-scale cleanrooms? No, we will not. Will we achieve absolute "sterility" in the current generation of isolators? No, we will not, but we will experience a closer approach to the ideal by manufacturing in a germ-free environment. Technological improvements should be implemented when they are beneficial. We believe that when aseptic products are manufactured in compliance with industry practices that have existed for at least the past 20 years, they are reliably safe. Let us stop worrying about theoretical conditions that can neither be proven nor measured and focus instead on safety, which can be both proven and measured.

# Cell Culture Processes in Monoclonal Antibody Production

FENG LI, AMY SHEN, and ASHRAF AMANULLAH

## 7.1 INTRODUCTION

With the increasing number of therapeutic candidates, especially monoclonal antibodies (mAbs), entering early stage process development, biopharmaceutical companies are increasing looking at innovative solutions to deliver the pipeline. Time to market, cost effectiveness, and manufacturing flexibility while maintaining the desired product quality attributes are key issues in today's competitive market, where several companies are working on therapies for similar clinical indications. Because most antibody therapies require high doses over a long period of time, antibody manufacturing capacity remains a big challenge. There is a continuing need for developing high-yield processes to produce large quantities with cost and time efficiency to meet clinical requirements and pave the way toward commercialization. In response to this strong demand, the current trend in the antibody industry is to make continuous improvements to develop a high-titer upstream process in a timely manner. Mammalian cell culture is the dominant expression system for therapeutic antibody production. However, mammalian cells have been considered difficult to work with in term of manufacturability and scalability because of low yield, medium complexity, serum requirement, shear sensitivity, and so on. After a decade of development work in cell line, media, and bioreactor condition optimization, high titers up to approximately 5 g/l and cell densities of more than 20 million cells/ml have been recently reported in fed-batch processes [1,2]. Cell-specific productivity of more than 20 pg/cell/day can be routinely achieved for production cell lines. Enhancement of specific productivity per cell is achieved not only from selection of the highly productive clones but also from optimization of medium composition and bioreactor operation conditions.

Cell culture process development starts with cell line generation and selection followed by media and culture condition optimization in small-scale systems, including 96-well plate, shaker flasks, and bench-scale bioreactors, for high-

throughput screening purposes. After the process conditions are defined, the process is often transferred to the pilot scale to get scale-up information and to produce toxicology materials and later to current good manufacturing process (cGMP) manufacturing for production of clinical material. As development of a commercial cell culture process for production of a biological product is completed at the laboratory and pilot scales, the commercialization process begins with process characterization, scale up, technology transfer, and validation for the manufacturing process. The strong demand for therapeutic antibody production, relatively modest titers, and reduction of cost of goods has resulted in a trend toward large-scale manufacturing. Today the largest biotech companies are using several hundred to 2000-l scale bioreactor for early clinical production and 10,000- to 25,000-l stirred tank bioreactor to produce commercial products.

## 7.2 MAMMALIAN EXPRESSION SYSTEM AND CELL LINE ENGINEERING

### 7.2.1 Expression Systems

Therapeutic antibodies are mainly produced in mammalian host cell lines, including murine myeloma cells, PER.C6 human cells, and Chinese hamster ovary (CHO) cells [3]. The choice of which expression system to choose is determined by an individual company's experience and by the host cell's ability to deliver high productivity with acceptable product quality attributes.

***7.2.1.1 NS0 Expression System*** Murine NS0 cells are non–immunoglobulin-secreting myeloma cells and are cholesterol auxotrophs requiring the presence of cholesterol in culture medium for growth [4]. However, cholesterol-independent NS0 cells also have been established [5–7]. NS0 cells lack endogenous glutamine synthetase (GS) enzyme activity, making them suitable for use with GS as a selectable marker for recombinant antibody expression [8]. However, antibody production up to 3 g/l has been reported from non-GS NS0 cell lines as well [9,10]. Most mouse-derived cell lines, including NS0, produce *N*-glycosylneuraminic acid (NGNA), a sialic acid that does not exist in human antibodies and that might be immunogenic in humans [11,12]. Although NS0 cells have been used in industry to produce therapeutic antibodies, this immunogenicity concern might at least partially make NS0 cells not as widely used as CHO cells for therapeutic antibody production.

***7.2.1.2 PER.C6 Expression System*** Compared with NS0 and CHO cells, PER.C6 cells are a relatively new technology and are derived from human embryonic retina cells, which have been immortalized by transfecting the E1 genes from adenovirus 5 DNA [13]. PER.C6 cells can proliferate indefinitely in suspension under serum-free conditions similar to NS0 and CHO cells. Their human origin might favor the argument that it is advantageous to produce therapeutic antibodies in PER.C6 cells because the posttranslational modifications are human-like and might be less immunogenetic. However, the human origin may make cells more vulnerable

to adventitious agents that can infect humans and cause diseases. This may raise some safety concerns and require more stringent requirements for cell line characterization and downstream viral removal capability.

***7.2.1.3 Chinese Hamster Ovary Expression System*** CHO cells are the predominant host used to produce therapeutic proteins. About 70% of all recombinant proteins [14] produced today are made in CHO cells, including DUXB11, DG44, and CHOK1 cells. Whereas DUXB11 and DG44 cells do not have dihydrofolate reductase (DHFR) activity, CHOK1 cells have endogenous DHFR activity.

A stable cell line development process starts with expression vector construction and transfection. After being transfected with plasmids bearing the antibody light chain gene, the heavy chain gene, and a selectable marker or markers, the cells are screened for highly productive cell lines after growth recovery, serum-free suspension adaptation and amplification (if necessary), and clone selection. To screen and select a highly productive and stable clone from the transfectant population in a limited time frame is a major challenge. These steps are further described below.

### 7.2.2 Cell Line Development

***7.2.2.1 Expression Vector*** The first step in developing a stable antibody-producing cell line is to construct an expression vector. Typically, the mammalian expression vector contains a cassette for the antibody genes, selectable marker gene (s) in mammalian cells, and a second cassette for the genes enabling plasmid replication in bacteria. To achieve a high level of antibody expression, strong promoter–enhancers, such as the cytomegalovirus (CMV) promoter [15] and elongation factor alpha (EF1$\alpha$) promoter [16], are typically used to drive antibody heavy chain and light chain expression. Often an intron sequence in the 5′ untranslated region is included after the promoter–enhancer to increase the export of transcribed messages to the cytoplasm from the nucleus, and one or more 3′ polyadenylation signal sequences are also included to maximize mRNA levels. Commonly used polyadenylation signal sequences are the SV40 late or early polyadenylation signal sequences and the bovine growth hormone polyadenylation sequence. In addition to transcription, translation and secretion are also required for antibody production. Typically, a consensus Kozak sequence [17] is created by placing GCCGCC(A/G)CC immediately in front of the first translation initiation codon to enhance translation initiation, and a signal peptide sequence is placed immediately in front of the mature antibody peptide to direct antibody secretion [8].

***7.2.2.2 Transfection and Selection*** A variety of transfection methods have been developed to stably introduce vector DNA into mammalian cells, including calcium phosphate, electroporation, cationic lipid-based lipofection, and the polymer- or dendrimer-based methods [18]. All four methods have been used for stable transfection, but electroporation and lipofection are the most common choices. Transfected cells are then selected, relying on different selectable markers that can be

**TABLE 7.1 Selectable Makers Often Used in Mammalian Expression Vectors**

| Selectable Marker | Selective Reagent |
|---|---|
| ***Metabolic Selectable Markers*** | |
| Dihydrofolate reductase (DHFR) | Methionine sulfoximine (MSX) |
| Glutamine synthase (GS) | Methotrexate (NTX) |
| ***Antibiotic Selectable Markers*** | |
| Puromycin acetyltransferase | Puromycin |
| Blasticidin deaminase | Blastcidin |
| Histidinol dehydrogenase | Histidinol |
| Hygromycin phosphotransferase | Hygromycin |
| Zeocin resistance gene | Zeocin |
| Bleomycin resistance gene | Bleomycin |
| Aminoglycoside phosphotransferase | Neomycin (G418) |

categorized into two groups, metabolic selectable markers and antibiotic selectable markers. Some commonly used selectable markers are listed in Table 7.1.

CHO stable cell lines have often been selected using metabolic selective markers, including methotrexate (MTX) (dihydrofolate reductase gene mediated) and methionine sulphoximine (MSX) (GS gene mediated) [8]. Table 7.2 shows a selected list of approved antibody products produced in CHO cells. It has also been reported that an antibody-producing cell line can be generated using two different selectable markers together [9]. In such cases when two selective markers have been used to select stable antibody-producing cell lines, the selective markers are either located in one expression construct also containing genes for heavy chain and light chain or are

located on two separate plasmids, each containing either the heavy chain or light chain gene.

Recently, we have explored the "double selection" approach, which simultaneously transfects two plasmids into CHO cells for stable antibody cell line generation. The unique feature of this approach is that each plasmid contains both the heavy chain and light chain genes and one selective marker. Cells transfected with two plasmids are selected with two different selective reagents such as MTX and MSX. The productivity of clones generated using this approach resulted in higher productivity than clones transfected with either plasmid alone, as shown in our 96-well productivity assay (Fig. 7.1). To our knowledge, this is the first time that simultaneous transfection with two expression constructs and selection with two different selective markers has been successfully demonstrated as a means to generate highly productive stable CHO cell lines expressing antibody.

***7.2.2.3 Stable Cell Line Screening*** To generate stable cell lines with adequate productivity for clinical or commercial material production, typically hundreds to thousands of clones are screened. The primary screen is usually an enzyme-linked immunosorbent assay with or without cell number normalization to eliminate non- or low producers. While high producers are scaled up, additional assays are performed to measure cell growth, cell-specific productivity, and volumetric productivity (titer) to choose the top 12 to 24 clone candidates, which are typically further analyzed in a fed-batch cell culture scale-down models such as shake flasks or laboratory scale bioreactors. Cell growth, specific productivity, volumetric productivity, product quality (often including glycosylation profile, charge variants, aggregate levels,

and protein sequence heterogeneity), and clone stability are assessed to pick the top four to six clones for further evaluation in bioreactors to choose the final production clone and backup clone (refer to Section 7.4.1).

### 7.2.3 Cell Line Engineering

A significant amount of work has been done to genetically engineer the production host cells to improve or modify the product quality or to improve the host cell robustness. One area that has received a lot of attention is glycosylation control because glycan structures on antibodies can have substantial effects on clearance rate and bioactivities [19]. Antibodies produced in CHO cells typically have complex biatennary structures with very low or no bisecting *N*-acetylglucosamine (bisecting GlcNAc) and high levels of core fucosylation [20]. Overexpression of *N*-acetylglucosaminyltransferase III has been used to increase the fraction of bisecting GlcNAc that resides on antibodies to improve antibody-dependent cellular cytotoxicity (ADCC). RNA interference (RNAi) and gene deletion technologies have also been used to decrease or eliminate the fucose on antibodies to dramatically increase ADCC activity [21,22]. Other areas of host cell engineering include approaches to decrease programmed cell death, to reduce lactate accumulation, and to manipulate cell growth. Overexpression of antiapoptotic gene or genes and RNAi technology–mediated knock-down expression of apoptotic gene or genes have been used to extend the culture viability, leading to the improved productivity [23]. Because CHO cell and other continuously cultured cells have low efficiency to completely oxidize glucose to $CO_2$ and $H_2O$, one of the byproducts of the cell culture process is lactate accumulation, which could cause the acidification of culture medium and lead to high osmolarity and low viability caused by the alkali added to control the medium pH. A significant amount of work [24–26] has been performed to reduce lactate accumulation. However, the usefulness of this approach may be very much clone dependent [26].

## 7.3 CELL LINE AND CELL BANK TESTS

Cell line testing is a critical component of the quality control system for the production of mAbs. Production cell lines need to be qualified at different stages of product development to ensure consistent product quality, cell line purity, and cell line stability. After cell line development through transfection, amplification, and final clone selection, a master cell bank (MCB) and a working cell bank (WCB) are created. The history of the host cell lines in terms of their original source, cultivation history, and the record of animal-derived raw material usage should be documented. Cell line transfection, selection, and subcloning methods are also described in regulatory documents. Antibody production cell banking typically uses a two-tiered cell banking system in which the MCB is created first either from an initial clone or from a preliminary cell bank derived from an initial clone, and the WCB is then generated from the MCB [27,28]. Both the WCB and MCB can provide the cell

supply for a product manufacturing campaign. Whereas the MCB is usually used in early stage clinical phase I and II manufacturing, the WCB is used in phase III and commercial manufacturing. To preclude contamination with cell lines of the same or other species of origin, the MCB and WCB should be created under cGMP, and no other cell lines should be handled or be present in the same cell banking suite.

### 7.3.1 Testing for Master Cell Bank, Working Cell Bank, End-of-Production Cells, and Cells at the *In Vitro* Cell Age Limit

As the production cell lines move forward from the cell line development to different phases of cGMP manufacturing, various tests are required to characterize and qualify the cells at different stages from the MCB to the cells at the *in vitro* cell age limit. The production cell lifespan from cell line generation to the *in vitro* cell age limit is illustrated in Figure 7.2.

As the original cell source to ensure an adequate supply of equivalent cells for production during the entire lifespan of the product, the MCB is subject to intensive testing to demonstrate cell identity and freedom from adventitious agents. Because the WCB is derived from one or more ampoules of the MCB and expanded by a few passages, full retesting for virus contamination is typically not necessary. Besides MCB and WCB testing, end-of-production (EOP) cells should be tested to further evaluate whether new contaminants have been introduced during manufacturing operations or induced by the process conditions. The testing of cells at the *in vitro* cell age limit should be performed at least as the product moves into commercial production. Based on the International Conference on Harmonization of Technical Requirements for the Registration of Pharmaceuticals for Human Use (ICH) guideline, the definition of *in vitro* cell age is the measure of time between thaw of the MCB vial(s) to harvest of the production vessel measured by culture time, by population doubling level of the cells, or by passage level of the cells [29]. The limit of *in vitro* cell age for production should be set based on data derived from production cells expanded under pilot plant scale or full-scale conditions to the proposed *in vitro* cell age or beyond. The tests to support establishing the limit of *in vitro* cell age are often done by extending the seed train culture to beyond potential manufacturing age and then using it to start a culture at either full scale or in a qualified scale-down model. Another way to generate aged cells is to collect cells from a full-scale production run and then passage them further in small scale until the cell age equals or exceeds the proposed limit. Cell line identity, genetic stability, and sequence of the product should all be addressed using these cells to define the maximum cell age for manufacturing product with acceptable performance and product quality attributes.

### 7.3.2 Cell Line Qualification Testing

For the purposes of clinical and commercial manufacturing, the cell banks and EOP cells need to be fully characterized and qualified before the release of bulk drug substance for market. The testing results are also required for submissions of the Biologic License Application (BLA), and some tests must be completed for the

**FIGURE 7.2** Cell line lifespan during product development. EOP: end-of-production; GMP: good manufacturing process; MCB: master cell bank; WCB: working cell bank.

investigational new drug (IND). In general, these tests can be categorized into cell line identity, purity, and stability as described in the next sections.

***7.3.2.1 Identity*** A cell line identity assay is used to demonstrate that the species of origin of banked cells or EOP cells is consistent with the species of the host cells. Isoenzyme analysis is commonly used to confirm cell line species of origin by checking electrophoretic banding patterns for a number of intracellular enzymes [30]. This analysis is often used for EOP cells and cells at the limit of *in vitro* cell age

to provide assurance of no cross-contamination with cell lines of other species during the cell culture manufacturing process.

***7.3.2.2 Purity*** This assay is used to demonstrate that the production banks are biologically pure and free from adventitious microbial and cellular contaminants. Intensive purity assays should be performed to test for sterility and to demonstrate the absence of *Mycoplasma* and viruses. Adventitious virus contamination can be present in the cell bank or can be introduced during production through contaminated raw material (e.g., animal-derived cell culture media component) and manufacturing operations. Moreover, most rodent cell lines used in antibody production are known to carry endogenous viruses. For example, CHO cell lines harbor levels of non-infections retrovirus, and NS0 is considered capable of producing an infectious retrovirus (murine leukemia virus). Retrovirus infectivity can be detected by incubating samples with detector cell lines, such as mink $S^{+}L^{-}$ cells and rat XC cells. These retrovirus infectivity assays are often performed in direct or extended format because low levels of infection that may not be detected by direct assays can be detected in extended assays by serial passage of inoculated detector cells to amplify low levels of retrovirus [31]. The level of retroviral-like particles (RVLPs) can be quantified by thin-section electron microscopy (TEM) or reverse transcriptase (RT) assays. These assays should be conducted for the EOP cells to establish the extent of virus clearance that the purification process should achieve. Because RVLP count could change with cell density and process conditions, EOP cells should be reexamined when significant changes in the production process are made [32] to ensure that RVLP levels present in cell culture fluid do not exceed the downstream viral clearance capability. Process conditions affecting the RVLP expression in CHO cells have been extensively tested. Such studies concluded that RVLP specific productivity (particles produced per cell per unit time) is an intrinsic property of individual cell lines. Only cell culture process changes (e.g., temperature and pH shifts, butyrate addition) that alter the cell physiological state can impact RVLP specific productivity. In these cases, the EOP RVLP recount is recommended. Other operational changes (e.g., bioreactor scale, seed density, feed volume) do not generally impact RVLP-specific productivity. Therefore, the potential to increase RVLP levels can be estimated based on the increase in accumulated cell mass [33].

***7.3.2.3 Stability*** Cell line stability can be assessed from the phenotypic, genotypic, and product quality changes as a function of *in vitro* cell age. Phenotypic stability is established by evaluating cell growth and productivity after serial cultivations. A common approach is to passage cells in seed train medium to mimic the production seed culture process. Periodically, production process cultures in a scale-down model are initiated with aged cells to assess the process performance with regard to viable cell density, viability, titer, and specific productivity. Genotypic stability can be tested by assessing the cell expression construct, which should be analyzed in the MCB and at the limit of *in vitro* cell age to establish that the correct coding sequence is maintained in the production cell line during the manufacturing campaign. The gene copy number and integration site can be assessed by quantitaive

polymerase chain reaction and Southern blot, respectively. The fidelity of the product gene transcripts can be determined by cDNA sequencing. Because cDNA sequencing cannot detect low levels of protein sequence variants, protein amino acid analysis by peptide mapping with liquid chromatography/tandem mass spectrometry (LC/MS/MS) can be used to demonstrate that the protein amino acid sequence does not change during the cell culture process.

There is no defined guidance on how to apply these assays to different cell lines because the cell line testing requirements often vary case by case because of the complexity of product development stages, specifics of different cell types, and country-dependent regulatory requirements. Table 7.3 summarizes the cell line testing requirements for MCB, WCB, EOP cells, and cells at *in vitro* age limit during late stage product development as an example. In this case, the production cell line is derived from a NS0 host obtained from the European Collection of Cell Cultures (ECACC). The isoenzyme assay is used in every stage from the MCB to the cell age limit to confirm the species origin. Tests for sterility (bacteria and fungi) and *Mycoplasma* are also applied to every stage because these adventitious contaminants can be introduced any time during the cell culture operation. Adventitious virus tests include routine *in vitro* and *in vitro* virus tests. Mouse antibody production and bovine virus tests are also added to test adventitious virus because of the host cell species origin and the contact of the host cells with bovine serum during the initial cell line development. All of the tests for the presence of adventitious virus are performed on the MCB but not all of them on the WCB. Routine *in vivo* and *in vitro* tests are also performed for EOP cells and cells at the *in vitro* age limit. Endogenous virus tests include TEM, extended $S^+L^-$, and extended XC plaque, which are performed on the MCB but not on the WCB. TEM assay is also used for EOP cells and cells at the *in vitro* age limit to estimate RVLP levels. Cell line stability is assessed through phenotypic (cell growth and productivity), genotypic, and product identity tests. Cell growth and productivity are tested at all stages as they are in-process control assays. Product identity testing by peptide mapping with LC/MS/MS is performed for the antibody product purified from cell culture fluid derived from EOP cells and cells at the *in vitro* age limit. Genetic analysis of the expression construct in terms of cDNA sequence is performed for MCB, EOP cells, and cells at the *in vitro* age limit to demonstrate that the expression construct structure does not change during the cell culture process.

## 7.4 PROCESS DEVELOPMENT, SCALE UP, AND TECH TRANSFER

Because of the high level of uncertainty of biopharmaceutical clinical studies, process development is often divided into early stage and late stage with different focuses. The responsibility of early stage development is to develop bioprocesses to produce materials for phase I and II clinical trials and animal toxicology studies. To accelerate IND filing for "proof of concept" clinic studies, it is becoming increasingly necessary for companies to deliver the pipeline efficiently with streamlined cell culture platform processes using standardized process conditions and procedures.

**TABLE 7.3 Cell Line Qualification Testing Requirements During Late Stage Product Development**

| Assay | Test Purpose | Specification | Stage | | | |
|---|---|---|---|---|---|---|
| | | | MCB | WCB | EOP | Cell Age Limit |
| Isoenzyme | Cell line identity | Consistent with species origin | √ | √ | √ | √ |
| Sterility | Microbial contamination | No growth | √ | √ | √ | √ |
| *Mycoplasma* | *Mycoplasma* contamination | None/detected | √ | √ | √ | √ |
| *In vitro* adventitious viruses | Routine adventitious virus | None/detected | √ | | √ | √ |

The use of platform process allows the acceleration of early stage cell culture process development activities such as clone selection, process lock, and tech transfer to clinical manufacturing with increased efficiency. The similarity of molecular characteristics and properties among different mAbs makes process platform approach feasible, although the processes may not be fully optimized for every molecule. As the product moves into the late stage for phase III and commercial production, the processes can be further optimized during the time frame between early phase and late phase production when clinical studies are being conducted. Late stage process development is then focused on improvements of process yield, robustness, scalability, and regulatory compliance. With process changes during both early and late stage development, product quality and comparability need to be closely monitored for patient safety. To gain biologics license application (BLA) common technical document (CTD) regulatory approval for commercialization, the processes also need to be characterized to evaluate the effects of process parameters on process performance and product quality and then validated to demonstrate process consistency before commercial cGMP production. Figure 7.3 illustrates the process development activities at different clinical development stages.

A cell culture process is composed of three parts: cell line, cell culture media, and bioreactor environmental conditions. Therefore, the cell culture process optimization is an integrated activity involving clone selection, medium development, and bioreactor condition optimization. After the cell culture process is locked, it needs to be transferred from the development laboratory to a production facility. In early stage development, speed to clinical studies is critical, and toxicity and phase I and II

**FIGURE 7.3** Clinical and process development flowchart. BLA: Biologic License Application; cGMP: current good manufacturing process; IND: investigational new drug; MFG: manufacturing; POC: proof of concept.

material deliveries are often on the critical path. In the late stage, costly large-scale production runs are deferred until results from early clinical trials are available. After the product succeeds in its pivotal clinical trial, speed to market becomes critical to achieve commercial success. This approach does not allow much time for engineering and shakedown runs. Therefore, successful scale up in a limited time frame is highly desirable.

### 7.4.1 Clone Selection

Selection of the final production clone is often considered one of the most critical decisions in cell culture process development because changing production cell line during clinical development is considered a major process change, which requires considerable efforts to demonstrate product comparability before and after the change. For example, changing the cell line after phase III production typically requires additional human clinical studies. Thus, it is important to select the right clone before phase III clinical production and preferably at the phase I stage.

As described in Section 7.2.2, after being transfected, the cells are diluted and cultivated in 96-well plates with a basal growth medium and screened for clones with robust cell growth and high productivity. The selected clone candidates based on productivity and growth characteristics are then adapted to production media and suspension culture. At this stage, to predict clone performance in large-scale production bioreactor, an enriched medium similar to the final production medium formulation with a similar feeding regimen can be applied in shake flasks or small-scale bioreactors. Several clone attributes should be considered and evaluated, including product quality, manufacturability, and productivity.

***7.4.1.1 Product Quality*** Maintaining consistent and comparable product quality is often challenging because of changes of cell line, process, and scale conditions as product candidates are moved forward from development laboratory to pilot plant and cGMP manufacturing. Among these variable conditions, the product cell line has the most significant impact on many quality attributes because some product quality attributes are often clone dependent. Table 7.4 summarizes some common analytical assays and quality assessment criteria used during clone selection to test mAb molecular properties such as sequence homogeneity, charge variants, aggregation, and glycosylation.

***7.4.1.2 Productivity, Stability, and Scalability*** Process yield obviously is another critical criterion to select the production clone. Because antibody expression rate in mammalian cells is non–growth associated, the final titer is equal to specific productivity $Q_p$ multiplied by the integral of viable cell density over culture duration ($\text{Titer} = Q_p \cdot \int X \, dt$). In today's industry standard, a production cell line could have a specific productivity from 20 to 80 pg/cell/day and peak viability cell densities from 5 to $20 \times 10^6$ cells/ml in a 10- to 14-day fed-batch process. Cell line stability is another factor that needs to be considered. It is sometimes found that productivity declines as cell age increases for some cell lines. Unstable clones are not suitable for

**TABLE 7.4 Product Quality Assessment During Clone Selection**

| Quality Attribute | Analytical Assay | Quality Assessment Criteria |
|---|---|---|
| Molecule integrity | cDNA sequence (qPCR), peptide map (LC/MS/MS), CE-SDS, or SDS-PAGE | Avoid amino acid sequence mutation and truncated antibodies |
| Aggregation | SEC | Avoid high level of aggregation, which could be immunogenic |
| Glycosylation | HPLC- or CE-based glycan assay | Avoid high levels of unusually glycosylation forms |
| Charge heterogeneity | IEF or iCIEF, IEC, HPLC | Avoid usually high levels of acidic or basic variant or extra acidic or basic peaks |

CE: capillary electrophoresis; HPLC: high-performance liquid chromatography; iCIEF: imaged capillary isoelectric focusing; IEC: ion-exchange chromatography; IEF: isoelectric focusing; LC: liquid chromatography; MS: mass spectrometry; qPCR: quantitative polymerase chain reaction; SDS-PAGE: sodium dodecyl sulfate polyacrylamide gel electrophoresis; SEC: size exclusion chromatography.

large-scale production because the cell culture process is scaled up through serial culture passages of the seed train and inoculum train, and therefore the cell age increases with scale. In addition, cell growth and metabolic characteristics, which can impact cell culture process robustness and scalability, also need to be assessed. For example, robust cell growth with high viability is desirable, but high lactate-producing clones are not preferable to avoid dramatic culture pH changes.

Screening and selection of highly productive and scalable clones among the transfectant population in a limited time frame are still major challenges because the product quality, productivity, and even cell metabolic profiles often depend on cell culture conditions. As described in Section 7.5.2, using miniaturized high-throughput bioreactors with full-process parameter controllability to mimic the large-scale bioreactor environment can help to identify the best production clone at the very early stage.

### 7.4.2 Medium and Feeding Strategy Development

In general, medium development for a fed-batch process involves batch medium and feed concentrate development as well as feeding strategy optimization. Optimization of cell culture media is often considered as cell line dependent and needs to be based on the metabolism and nutrient consumption by a specific cell line. Several approaches can be used systematically, such as single-component titration, spent medium analysis, and medium blending [34]. Because of safety concerns for transmissible spongiform encephalopathy (TSE) and other transmissible contaminants, bovine serum and animal-derived raw materials should be avoided if possible. After two decades of media development and host cell adaptation, fully chemically defined media consisting of amino acids, vitamins, trace elements, inorganic salts, lipids, and insulin or insulinlike growth factors have been developed and implemented in large-scale mAb production. But not all antibody production cell lines can achieve

high yield in fully chemically defined media. Addition of animal component–free hydrolysates to the chemically defined media is a common approach to increase cell density, culture viability, and productivity in a timely manner. Hydrolysates are protein digests composed of amino acids, small peptides, carbohydrates, vitamins, and minerals, which provide nutrient supplements to the media. In addition, hydrolysate peptides can also act as growth factors and production stimulators. Non–animal-derived hydrolysates from soy, wheat, and yeast are commonly used in cell culture media and feeds. However, because of its composition complexity and lot-to-lot variations, hydrolysate can be a significant source of medium variability.

The most common approach to develop a feed medium is to concentrate basal media without salts to avoid high osmolality. Some key feeding components such as phosphate have also been identified [35]. During medium preparation, pH, temperature, or both may need to be adjusted to completely dissolve some low-solubility components [36]. Optimization of a feeding strategy needs to consider nutrient consumption, byproduct accumulation, and growth–production balance. Previous studies indicated that byproducts such as lactate and ammonia could be minimized by maintaining low-glucose and low-glutamine concentrations through frequent feeding [37]. However, the operation complexity for frequent or continuous feeding makes it less desirable for large-scale manufacturing, although this should not be a major challenge because they are routinely applied to microbial fermentations. Stepwise bolus addition of the feed solution to the production bioreactor is most widely used in industry because of its simplicity and scalability. In general, medium development is labor intensive and time consuming. A combination of high-throughput cell culture scale-down systems with statistical design of experiment approaches is commonly applied to shorten the development time.

### 7.4.3 Bioreactor Optimization and Scale Up

A typical stirred tank bioreactor is equipped with temperature, pressure, agitation, pH, and dissolved oxygen controls. Culture operating parameter optimization is required to achieve high expression of product with acceptable product quality profiles. These parameters are physical, chemical, and biological in nature. Physical parameters include temperature, gas flow rate, and agitation speed, and chemical parameters include dissolved oxygen and carbon dioxide, pH, osmolality, redox potential, and metabolite levels, including substrate, amino acid, and waste byproducts. Biological parameters are used for determining the physiological state of the culture and include viable cell concentration, viability, and a variety of intracellular and extracellular measurements such as NADH (nicotinamide adenine dinucleotide + hydrogen), lactate dehydrogenase levels, mitochondrial activity, and cell cycle analysis. Variations in the microenvironment parameters from optimal levels can have a dramatic impact on culture performance, productivity, and product quality. Figure 7.4 illustrates the cell culture operating parameters' impacts on the culture environments such as dissolved oxygen (DO), pH, osmolality, dissolved $CO_2$, mixing, hydrodynamic shear, and process performances (e.g., cell growth, metabolite concentrations, product titer, product quality).

**FIGURE 7.4** Cell culture process operating parameters affect process performance and product quality.

Because of the complexity of protein products with isoforms and microheterogeneities, the performance of the cell culture process can have significant impacts on product quality and potency, especially with respect to glycosylation, post-transcriptional modifications, and impurity profiles. Therefore, the bioreactor operating parameters have to be optimized and characterized thoroughly to improve process performance and to understand the process impact on product quality. Significant progress has been made in the past two decades in understanding the impact of the cellular environment on culture physiology and its subsequent impact on productivity, product quality, and downstream processes. Another reason for the resurgence of research activity and innovation in this area can be attributed to the Food and Drug Administration's (FDA) process analytical technology (PAT). The PAT directive (http://www.fda.gov/Cder/OPS/) is a framework for controlling manufacturing consistency and product quality through measurements and control of (both online and offline) of critical quality attributes of materials as well as processes. In addition, it also encourages a better understanding of the manufacturing process, identifying relationships among process parameters and reproducibility, culture performance, and product quality attributes. Although originally conceptualized for small molecule manufacturing processes, it is increasingly being extended to biological processes, which are inherently more complex because of the nonlinear impact of a large number of variables.

Process parameters can be measured either online (or at-line by direct connection to calibrated analyzers) or offline via operator intervention. Typical examples of

offline measurements include pH (usually for verification of online pH readings and compensation for sensor drift), cell counting and viability measurements using a hemocytometer or automated cell counters, packed cell volume, osmolality, and metabolites. Accurate gas and liquid flow measurements are typically conducted using mass flow meters and magnetic meters.

Temperature can be measured accurately using commercially available resistance temperature devices, although thermocouples can also be used. A temperature shift to manipulate the cell cycle in CHO cell culture has been reported to extend culture longevity. A temperature shift from 37 to 30°C after 48 hours postinoculation can retain cells in G1 phase longer and therefore delay the onset of apoptosis [38].

Dissolved oxygen is typically between 20 and 50% air saturation to prevent dissolved oxygen limitation and excessively high values that can lead to cytotoxicity. The Clark-type electrode is still the most commonly used for dissolved oxygen. In this type of electrode, oxygen diffuses through a permeable membrane and is reduced at a negatively polarized cathode (platinum) with respect to a reference anode. The cathode and anode are separated by an electrolyte solution, and the reduction of oxygen generates a voltage-dependent current that is directly proportional to the dissolved oxygen concentration. Although cell growth is relatively insensitive to dissolved oxygen in the range 20 to 100% air saturation [39,40], the dissolved oxygen level could have significant impact on product quality. It has been reported that reduction in dissolved oxygen caused a decreased glycosylation of antibody *N*-glycan chains [41].

Dissolved $CO_2$ is also an important process variable that can accumulate to inhibitory levels at values greater than 120 to 150 mm Hg [42–44] or impact product quality at high cell density cultivations or scale up because of inadequate $CO_2$ stripping. Commercially available sensors are available from Yellow Springs Instruments (YSI, Yellow Springs, OH) and Metler Toledo (Columbus, OH). However, in many cell culture processes, dissolved $CO_2$ is still measured using offline blood gas analyzers such as those from Nova Biomedical (Waltham, MA). The use of the *in situ* sensors could allow for the online control of dissolved $CO_2$ via air sparging, although this is rarely implemented in cell culture applications, perhaps because of the interrelationship of air sparging and dissolved oxygen control or that it is generally possible to match $CO_2$ profiles at small and large scales by the correct choice of bioreactor sparger design, agitation speed, and gas sparge rates. Measurement of oxygen uptake and $CO_2$ production rates can also be achieved using online MS (generally multiplexed to multiple bioreactors). Unlike microbial fermentations, this type of analysis is rarely conducted either because of the cost of such instrumentation or the sensitivity of measurements at very low rates of metabolism.

For mammalian cell culture, pH is an important variable to measure and is normally controlled tightly. Even a small deviation of 0.1 unit from the optimal pH value can significantly impact culture growth and metabolism, particularly glucose consumption and lactate production [45,46]. High pH ($\geq$7.0) is usually preferred for initial cell growth; however, a high pH condition is also associated with increased glucose metabolism by converting more glucose into lactate. When lactate accumulation exceeds the medium buffer capacity, the culture medium pH decreases.

Because most processes control pH at a certain level, lower pH of the culture medium triggers base addition to the culture, which increases the osmolality of the culture medium. This high pH, high lactate, and high osmolality cascade often causes delayed cell growth and accelerated cell death. Thus, the pH control condition needs to be optimized at the beginning of the cell culture process to maximize the initial cell growth. When fast cell growth is achieved, the pH set point can be shifted to a lower level to avoid lactate accumulation and to facilitate antibody production. It is also important to note that the pH set point and control strategy (e.g., dead band) are intimately linked to dissolved $CO_2$ levels and base consumption for pH control and therefore osmolality. These considerations make the accurate measurement of pH even more imperative. pH probes typically consist of a 0.2- to 0.5-mm glass membrane fabricated from silicate groups containing sodium, which form a hydrated gel layer on sides of the membrane when placed in liquid. An $Ag/AgCl_2$ electrode in KCl electrolyte saturated with $AgCl_2$ is used to measure the change in potential of the outer surface of the membrane caused by changes in the medium pH. Some issues related to the use of pH probes for extended culture duration include drift and reduced sensitivity.

Most cell culture media are designed to have an osmolality in a range of 270 to 330 mOsm/kg. The impact of osmolality is cell line specific, with reports of growth inhibition with increasing osmolality but no effect on cell specific productivity [47]. In many cases, it is difficult to decouple the impact of dissolved $CO_2$ and culture osmolality. Culture osmolality is routinely measured using freezing-point depression osmometry. In this method, the total osmolality of an aqueous solution is determined by comparing the freezing point of pure water and the freezing point of the sample. For example, water has a freezing point of 0°C, and a solution with saline concentration of 1 Osm/kg has a freezing point of −1.86°C. Various commercial systems are available, although the analyzers from Advanced Instruments (Norwood, MA) are the most commonly used in cell culture and are capable of measuring osmolality in the range of 0 to 1500 mOsm/kg of water.

Cell culture metabolites such as glucose, lactate, glutamine, and glutamate are commonly measured offline using enzymatic biosensors specific to the measured analyte. These measurements are important not only for maintaining substrate levels above critical levels via feeding strategies but also in developing processes with reduced byproduct formation. Commercially available instruments include the YSI 2700 from YSI Nova Bioprofile 400 from Nova Biomedical. These analyzers use biosensors in which the reaction of a substrate with the enzyme produces a product that can be readily measured. For example, glucose can be detected using glucose oxidase in the presence of excess oxygen to produce gluconic acid and hydrogen peroxide. A second reaction between fluorescein and the $H_2O_2$ produced from the first reaction produces a fluorescent signal that correlates directly to the glucose concentration. In addition to the quantification of metabolites, the Nova Bioprofile 400 can also measure pH, dissolved gases ($O_2$ and $CO_2$), $NH_4^+$ (0.20–25.00 mM), $Na^+$ (40.0–220.0 mM), $K^+$ (1.00–25.0 mM), and $Ca^{2+}$ (0.10–10.0 mM). It is important to point out that accurate measurements with these systems require proper maintenance and calibration procedures.

Cell concentration and viability measurements are critical in developing cell culture processes and are used for determining culture physiology in response to operating conditions and calculation of growth rates, specific consumption and production rates of metabolites, and cell-specific productivity. The most common method for measuring cell concentration and viability is via trypan blue exclusion microscopy. This method depends on the ability of cells with intact membranes to exclude trypan blue (live cells), and those that are stained blue are classified as dead cells. A number of automated analyzers exploiting this method and coupled to image analysis are commercially available (Cedex, Innovatis, Bielefeld, Germany; Vi-Cell, Beckman Coulter, Fullerton, CA). These analyzers also allow the determination of cell size. In many cell culture processes, the mean cell size can change by as much as 50% (or more than a threefold change cell volume). In these cases, it is insufficient to measure viable or total cell concentration. Instead, packed cell volume (or viable packed cell volume) is determined using centrifugation-based hematocrit methods. This is a more accurate representation of the cell mass, which is ultimately linked to metabolite profiles and product formation. The trypan blue exclusion method does not allow measurements other than live or dead. Multiparameter flow cytometry using fluorescent dyes such as propidium iodide and annexin V or caspase 5 can be used to quantify live or dead cells as well as apoptotic cell populations. This is now possible in cell culture laboratory settings using relatively simple 96-well plate–based systems and specifically designed measurement kits for such analyses as well as a multitude of other cell-based assays (Guava Technologies, Hayward, CA). Measurements of cell metabolic activity can be quantified by online oxygen uptake rate measurements or offline cell mitochondrial activity using fluorescence-activated cell sorting (FACS).

Process scale up implements process at larger scale to achieve similar process performances as in small scale. A typical large-scale cell culture process consists of a number of unit operations, including seed train, inoculum train, and production run

| Manufacturing scale | 20 l | 80 l | 400 l | 2000 l | 12,000 l |
|---|---|---|---|---|---|
| Scale-down model | 2 l | 2 l | 2 l | 2 l | 2 l |
| Key performance parameter | Growth rate, final viability | Growth rate, final viability | | | Titer, product quality |

**FIGURE 7.5** A large-scale cell culture process steps and their key process performance parameters.

as described in Figure 7.5. Each step has its key process performance parameters such as cell growth, viability, titer, and product quality. The success of cell culture process scale up is measured by these key process parameters meeting their predefined criteria.

Mammalian cells are generally considered difficult to be scaled up because of their sensitivity to physicochemical conditions. Scale up of high cell density process to large-scale bioreactors by providing enough oxygen supply and $CO_2$ removal can be challenging in some cases and requires a proper selection of large-scale bioreactor operating parameters. Bioreactor operating parameters can be categorized into volume-dependent parameters (e.g., working volume, feed volume, agitation, aeration) and volume-independent parameters (e.g., pH, dissolved oxygen, temperature). A general strategy for scale up is to proportionally scale up the volume-dependent parameters while maintaining the volume-independent parameters at the same set points used in the small-scale process. However, some volume-dependent parameters are difficult to be scaled up or down linearly because of differences in bioreactor geometry, ratio of liquid surface to volume, gassing regimen, and control capability. During bioreactor operating condition scale up, agitation and aeration are two important conditions to be scaled up properly to achieve comparable process performance across different scales. Whereas agitation is required to provide sufficient mixing and oxygen mass transfer and is generally scaled using equal specific energy dissipation rate, aeration is used to supply of oxygen and remove of excess $CO_2$. In small-scale bioreactors, the operable ranges of operating parameters are wide because mixing is generally not a problem even at relatively low agitation speeds, and dissolved $CO_2$ removal is efficient because of a large surface-to-volume ratio. In large-scale bioreactors, these parameters need to be chosen carefully because agitation-related shear stress and aeration-related $CO_2$ accumulation increase with scale.

Besides large-scale bioreactor operation issues, other common pitfalls of cell culture process scale up include lot-to-lot variations of raw material, consistency of media preparation, media hold stability, and cell line stability during the long duration of manufacturing process as described previously. These issues can often be identified in scale-down models. A qualified cell culture scale-down model, which is able to reproduce large-scale process performance at small scale, provides crucial information needed to assess and resolve any unexpected performance problem of the large-scale system. Beyond manufacturing support, the scale-down model can also be used for process characterization and validation experiments to study acceptable ranges of process operating parameters and determine the critical operating parameters.

### 7.4.4 Process Characterization and Validation

The FDA defines process validation as "establishing documented evidence that a specific process will consistently produce a product meeting its predetermined specifications and quality attributes." For a biological product, all process validation data should be submitted and the specifications are established and approved as part of the BLA. This regulatory requirement reflects the recognition that the product

**FIGURE 7.6** Cell culture performance in a 2-l stirred tank bioreactor (□) and 250-l HyClone single-use bioreactor (SUB, ■): online pH (a), osmolality (b), viable cell concentration (c), percent viability (d), lactate concentration (e), and titer (f).

quality can be substantially affected by the manufacturing process. To meet this requirement, the process needs to be fully characterized and validated to understand the impact of process inputs (operating parameters) on process outputs (performance parameters). Figure 7.6 illustrates a typical cell culture manufacturing process and the key performance parameters of several unit operations, including seed train, inoculum train, and production. Because key performance parameters are often different for different cell culture steps, each operation usually needs to be characterized and validated separately. The full process characterization and validation usually occurs after the completion of phase III process development when the manufacturing process is locked and no further changes are expected. Although some process validation work can be performed using qualified scale-down models, full-scale process validation is required to demonstrate consistent process performance and product quality when controlling critical process parameters within predefined acceptable ranges at commercial scale. For validation purposes, normally three consecutive full-scale runs are required for BLA licensure in the United States.

The objectives of process characterization include identification of key operational and performance parameters, establishment of acceptable ranges for key parameters,

and demonstration of process robustness [1,48,49]. Technical information from the characterization study has also become a regulatory expectation in recent years as a prerequisite for manufacturing process validation as well as for long-term commercial manufacturing support [50,51]. Because performing a characterization study at the manufacturing scale is not practically feasible because of the cost of operation and limited availability of large-scale bioreactors, scale-down models that represent the performance of manufacturing scale process are usually used. It is also important to use qualified analytical methods and raw materials throughout the characterization study for consistency and accuracy. Cell culture process characterization requires support from the purification and analytical groups to test process impact and to monitor product quality. Some cell culture materials from characterization studies can be used as feed stream for downstream process characterization, especially for the robustness study.

### 7.4.5 Process Technology Transfer and Current Good Manufacturing Process Manufacturing

After a scalable process is locked at the laboratory and pilot scales, it needs to be transferred to a manufacturing facility for cGMP production of clinical or commercial quantity of product. The purpose of process technology transfer is to transfer of all of the necessary process technology, information, documentation, equipment, materials, and tools in order to implement the manufacturing process at a specific facility for clinical and commercial material production and obtain the regulatory approval.

The tech transfer typically requires collaborations among different groups, including process development, manufacturing, and quality. The activities required to successfully transfer a cell culture process can be organized into several stages, including:

1. Process–facility gap analysis
2. Process, facility, equipment modification, and qualification
3. Engineering runs at full scale if needed
4. cGMP commissioning
5. cGMP production (comparability study for process and product)

As a new process being introduced into an existing facility, a gap analysis should be conducted to identify the gaps and potential risks to fit the manufacturing process into the facility. The facility and equipment modifications and installation qualification/operational qualification/performance qualification (IQ/OQ/PQ) activities should be completed before the full-scale production runs. Moreover, as the product moving from early stage (phase I and II clinical) to late stage (phase III commercial) production at different scale facilities, the process may need to be modified to reflect scale and facility changes. In this case, the modifications should be minimized to changes needed to enable the facility fit and to focus on critical quality attributes and the changes need to be qualified and incorporated into the comparability evaluation to ensure the process and product quality consistency before and after manufacturing

site change. In general, regulatory authorities do not require that the pre- and postchange product is identical but rather that its physicochemical properties and biological activity are highly comparable and that these changes have no impact on the safety or efficacy of the product.

Non-GMP engineering runs are conducted to test process performance at full scale to ensure process and product quality consistency. Before the initiation of the cGMP production, cGMP commissioning should also be completed to make sure facility, raw material, documentation, personnel training, quality control, and production systems are ready.

## 7.5 PROCESS ADVANCES AND FUTURE PERSPECTIVES

### 7.5.1 Advances in Process Online Monitoring and Control

Monitoring of cell cultures is essential for the development and optimization of highly productive processes. In addition, the ability to develop control strategies depends on the availability of robust and accurate *in situ* sensors or at-line instruments coupled to a sampling system to measure relevant parameters. This section gives a brief discussion of the use of commercially available sensors, advances in optical and noninvasive sensor technologies, and autosampling systems to enable at-line monitoring.

***7.5.1.1 Dielectric Permittivity and Electrical Impedance Spectroscopy*** Offline measurements of cell mass do not easily permit the use of growth-based feedback control strategies for feeding. Online optical cell density probes based on light backscatter have been used successfully to monitor cell cultures [52]. Such measurements are generally linear with cell concentration only at high viabilities and deviate significantly from linearity with decreasing culture viability toward the latter stages of fed-batch cultures. Dielectric permittivity and electrical impedance spectroscopy can be used successfully to monitor viable cell volume [53]. These measurements make use of the fact that live cells consist of poorly conductive lipid membranes that separate a conductive cytoplasm from a conductive extracellular matrix. When an electric field is applied, the cells become polarized and behave as tiny electric capacitors. The capacitance of the cell suspension gives a measure of the extent of the field-induced polarization, which is related to the viable cell volume or concentration, provided the cell diameter does not change appreciably.

***7.5.1.2 Near Infrared Spectroscopy*** Spectroscopy, particularly using near or mid infrared (NIR or MIR), is an attractive alternative for the measurement of cell culture components, including substrates, waste products, amino acids, cell concentration, and viability. Sample preparation is not required, and this technique can be used to measure a large number of parameters simultaneously. A light source is introduced to the sample via a steam-sterilizable probe mounted using standard bioreactor ports. Up to nine channels are available on a commercially available unit

from Foss NIR Systems (Laurel, MD). The resulting transmittance measurement can be correlated to individual components and concentrations in a sample matrix. Because of the complex nature of the spectra, partial least-square (PLS) regression methods are used for deconvolution. Initially, the NIR spectral scans are trained using offline measurements of cell counts, osmolality, metabolites, and amino acids or other cell culture media components. This calibration model is then used to predict culture components in spectral scans in independent bioreactor cultures. Several studies have been published demonstrating the usefulness of this technique for monitoring cell culture media components [54–57]. Despite this, NIR is rarely applied in cell culture processes (even in a laboratory setting). This may be because the spectroscopic measurements (position and intensity of spectrum) are sensitive to changes in process parameters such as pH, ionic strength, and temperature. This is especially true for low-concentration components in the presence of a complex matrix background. Significant challenges remain for the successful application of this promising technology for cell culture monitoring in terms of establishment of robust calibration methods and PLS-based data analysis that can be implemented routinely by nonexpert operators.

***7.5.1.3 Noninvasive Fluorescence Sensors*** Noninvasive fluorescence sensor technologies have rapidly emerged as an important development for online monitoring of cell culture parameters such as optical density, pH, and dissolved oxygen, especially for microtiter plates for high-throughput applications [58]. Such sensors are commercially available from PreSens Sensing GmbH (Regensburg, Germany) and Fluorometrix (Stowe, MA). This technology has also been incorporated in optical probes for pH, dissolved oxygen, and dissolved $CO_2$ (Polestar Technologies Inc., Needham Heights, MA), Sartorius (Edgewood, NY), and YSI, as well in shake flasks (Fluorometrix and PreSens Sensing GmbH). The dissolved oxygen and pH detection uses dynamic luminescence quenching of the specific fluorophore by oxygen or protons per the Stern-Volmer equation [59]. These measurements use dual referenced optical sensing whereby the relative emission ratio is measured from the shared spectrum from an indicator fluorophore sensitive to pH or DO. The recessed and external light protected LEDs under the emit light at 470 nm for pH sensing and 505 nm for DO. Further research is ongoing to develop robust dissolved $CO_2$ sensors and biosensors for culture substrate and metabolites.

***7.5.1.4 Automated Sampling Systems*** In addition to online measurements, a number of measurements have to be conducted using offline analyzers with manual intervention, which increases contamination risks as well as places a burden on resources. However, such measurements can also be conducted at line using automated sampling systems and with data transfer to control systems can be used in control strategies. Until recently, there has been a paucity of commercial autosamplers, and when available, they have been limited to fraction collectors. In most cases, this requires operator intervention for sample analysis. Online sampling could fully eliminate the labor-intensive, low-value-added processes of manual reactor sampling and data entry and eliminate operator-introduced sampling

variability. However, autosamplers also pose concerns for increasing contamination risks, robustness, ease of use, and hold-up sample volume requirements (especially at small scales). Recently, Groton Biosystems (Groton, CT) has introduced four- and eight-bioreactor sampling systems (ARS400 and ARS800), which are capable of user-defined sterile sampling and can be connected up to four separate analytical devices. The system is also configured with cleaning and sanitizing reagents to allow a low bioburden environment in the sampling tubes. The sterility barrier between the analyzer and bioreactor contents is provided via a reactor valve interface.

### 7.5.2 Miniaturized High-Throughput Scale-Down Models for Cell Culture

To deliver a robust and productive process while maintaining aggressive timelines to introduce the molecular candidate in to the clinic, increasing throughput of bioprocess development has become progressively important to rapidly screen and optimize process parameters [60,61]. Traditionally, small-scale systems such as shake flasks and spinner flasks have been used to screen a large number of clones and experimental conditions. However, because of the inability to monitor and control environmental parameters and the inability to conduct fed-batch cultivations on a routine basis and the laborious nature of shake flask experimentation, these models are less desirable for bioprocess optimization.

De Jesus et al. [62] developed a scaled-down system for suspension cell culture, coined the "TubeSpin," using 50-ml centrifugation tubes as culture vessels mounted on rotational shakers. The TubeSpin can be configured with vented caps, thus allowing the exchange of gases via the headspace. Although this system does not permit the *in situ* measurement and control of pH and dissolved oxygen, it is nevertheless suitable for large screening experiments in which such information may not be crucial. It is also conceivable that the TubeSpin could be linked to a liquid handling system to allow an extension of its capabilities. A number of micro-bioreactors are also commercially available at scales of 50 to 300 ml (Fluorometrix, AC Biotech, Julich, Germany; Infors AG, Bottmingen, Switzerland; DASGIP, Julich, Germany). Bioprocessors Corp. (Woburn, MA) has developed a fully integrated robotics platform (Simcell) with its proprietary microbioreactor arrays (each array consisting of six gas-permeable microreactors with submilliliter working volumes) for true high-throughput cell culture applications. The Simcell system appears to be very promising and has been acquired by several companies. Although results have been presented at conferences [63], there are no published reports in the literature.

### 7.5.3 Disposable Cell Culture Technologies

Traditionally, stainless steel tanks have been used at laboratory and pilot scales for process development and production of research grade, toxicology, and phase I clinical materials. Stainless steel tanks also dominate large-scale manufacture (>1–25,000 l) of biotherapeutics. However, the use of fixed plant equipment is costly, requiring long lead times for installation of the tanks and supporting infrastructure

and qualification. There is also a high burden from validation efforts related to sterility and cleaning, as well as maintenance.

Disposable technologies offer significant advantages over traditional fixed plant equipment, particularly at pilot scales of operation. They can be introduced rapidly into a laboratory and manufacturing facility because installation, qualification, and personnel training efforts are minimal, require few utilities, are provided clean and presterilized, and offer increased reliability because of their one-time use. In addition, they can increase plant capacity and flexibility by reducing turnaround time (especially in the event of contaminations); decreasing set-up time; and demanding a smaller footprint because of significantly reduced piping, valve, and instrumentation requirements. Implementing design changes is also more rapid with disposables, allowing for continuous improvement and integration of new technologies such as online monitoring systems. Operational flexibility is essential because of changing priorities in development. In addition, facility change-over time and effort can be reduced, especially in cGMP applications in which preventing cross-product contamination is of crucial importance. Overall, these advantages lead to significantly lower capital costs and lower resource (personnel) requirements, which are key factors for both large and small companies alike.

Cell culture processes are becoming more productive because of advances in cell line engineering and process development, which in turn allows the use of smaller scales. As a result, disposables are gaining popularity. Use of disposables facilitates the production of gram quantities of research grade material, scale up, and handling of multiple products in a current good laboratory practice (cGLP) or cGMP facility for the manufacture of toxicology or even phase I material. Although disposable technologies in bioprocessing covers a wide range of components such as bioreactors, tubing and pipes, pumps, filters and membranes, valves, sampling devices, bottles, bags for media and buffer preparation, and sensors (to name a few) and the applications range from culture cultivation, purification (cell separation, buffer bags, in-process pool containment, prepacked chromatography columns), and bulk drug storage, the focus of this section is on single-use bioreactors (SUBs) for cell culture processes.

***7.5.3.1 Single-Use Bioreactors Integrated with Disposable Bags*** Single-use bioreactors at the laboratory and pilot scales (1–1000 l) incorporate disposable bag technology at the core of their design and are capable of providing mixing and mass transfer and control of process parameters (air flow rate, gas mixing, temperature, dissolved oxygen, pH) similar to conventional stirred tanks. Both traditional and noninvasive sensors have been used. These are described later. The bags are generally manufactured with class VI United States Pharmacopeia (USP) materials. For many years, liners and bags composed of these materials have been used for media make-up, storage, and transfer, so cultivating cells inside such materials should not be viewed as a substantial risk. Before the implementation and use of SUBs, they must be qualified in terms of extractables or leachables (e.g., total organic content) and vapor transmission from the material of construction of the bags used as well as integrity and sterility testing using standard methodologies such as the use of model solvents and media hold tests under processing conditions. This is

generally done with the complete bag design, which includes the bag, fittings, and tubing. The extractables or leachables information is also generally available from the vendors. In addition, SUBs have to be characterized in terms of their mixing, oxygen and $CO_2$ mass transfer, and process control capabilities (response time and accuracy) for dissolved oxygen, pH, and temperature.

There are several commercially available SUBs, and although not a comprehensive list, the companies marketing these systems include Wave Biotech (http://www.wavebiotech.com, now part of GE Healthcare), Sartorius (Edgewood, NY, http://www.sartorius.com), HyClone (http://www.hyclone.com), Hynetics (http://www.hynetics.com), ATMI (http://www.atmi.com), Xcellerex (http://www.xcellerex.com), Applikon (http://www.applikon-bio.com), and CELL-ution (http://www.cellutionbiotech.com). The systems differ in their methods of mixing, impeller integration (if one is used), aeration strategy, and probe incorporation. Two of these SUBs, the Wave Bioreactor and the HyClone, are described next.

***7.5.3.2 Wave Bioreactor*** One of the first SUBs introduced for cell culture applications was by Wave Biotech and was coined the Wave Bioreactor [64]. The Wave Bioreactor consists of a disposable bag, which contains cells and media, placed on a heated rocker. Headspace aeration is used to inflate the "cellbag," and the rocking motion ensures mixing and mass transfer. Oxygen mass transfer coefficients up to $60\,hr^{-1}$ at 30 rpm have been reported [65]. Dissolved oxygen and pH are measured by optical and polarographic probes, respectively. Gas blending to maintain dissolved oxygen and pH are supplied using mass flow controllers and integrated controllers. The manufacturers of this system, GE Healthcare Bioscience Bioprocess Corp. (Somerset, NJ), claim suitability for a wide variety of cell types and have manufactured units with up to 500 l of working volume. However, challenges exist with certain cell types, such as cholesterol-dependent cell lines [66], and mechanical issues have been noted at larger scales when repeatedly stopping and starting a 500-l wave of liquid places a major strain on the motor and rocker assembly.

GE also produces a system capable of operation under perfusion conditions. This system involves the use of a cell bag specifically designed for perfusion applications that contains an internal polyethylene filter. The floating 7-μm pore size polyethylene filter is approximately $100\,cm^2$ and allows the continuous withdrawal of cell-free spent medium from the system, which is replaced with fresh medium to maintain culture volume. Filter fouling, a common problem in membrane-based cell retention devices, is reduced because of the wave motion of culture fluid across the filter. Perfusion control based on constant culture weight relies on a load cell integrated into the Wave Bioreactor platform.

There are relatively few publications related to the Wave Bioreactor. Although publications exist on batch cultivation of mammalian, insect, yeast, and plant cells within the Wave Bioreactor [67–69], little literature exists regarding the use of this system for more intensive processes, such as fed-batch or perfusion operation. Pierce and Shabram [70] used Wave Bioreactors coupled to an external hollow fiber 0.2-μm pore size microfiltration cartridge for perfusion culture of a CHO-based cell line for

production of fusion protein at scales up to 500l. Very recently, Tang et al. [71] reported the use of a 1-l perfusion Wave Bioreactor for the production of IgG2 mAb using hybridoma cells. A number of similar wavelike systems, operating on similar principles, have been recently introduced, including those from Applikon, Sartorius, and CELL-ution. Although both systems from Applikon and Sartorious are equipped with invasive fluorescence-based optical dissolved oxygen and pH sensors (an improvement over the current sensors used in the Wave Bioreactor), the system from CELL-ution relies on more desirable noninvasive sensor technology. In addition, according to the manufacturer of this system, it is possible to obtain very high oxygen mass transfer rates because of the combined axial and vertical movement of the rocker.

***7.5.3.3 HyClone Single-Use Bioreactor*** The HyClone SUB, sold through Thermo Fisher Scientific, Inc., is intended as a retrofit product to replace the stainless steel bioreactor vessel in existing bioreactor skids rather than as a complete turn-key bioreactor system with integrated control systems. Alternatively, the HyClone SUB can be integrated using a number of customizable control systems such as Delta V. The current line of products consists of customizable 50-, 250-, and 100-l maximum working volume units. The disposable bags are mounted inside a permanent stainless steel jacket and secured by clips. Heat transfer is provided by an electrically heated jacket or customizable heat exchangers. The bags, made of class VI USP materials, are fitted with presterilized air inlet and vent filters (with optional heaters to prevent condensation) and ports for media/base addition and sampling. A single 45-degree pitched blade impeller made of molded polyethylene is linked to the seal–bearing assembly by C-flex tubing, which forms the contact material to the shaft. Aeration can be provided either via overlay or sparge. In the latter case, gas is provided by an integrated gas-permeable disc at the bottom of the bag. Overpressurization of the bag can be prevented using disposable pressure transducers linked to a control system. The sealing–bearing assembly links with the motor and allows impeller rotation while maintaining bag integrity. The bags can be used with presterilized conventional 12-mm sensors for pH and dissolved oxygen, which can be inserted in a sterile manner into the bag using novel quick connects. These sensors must also be connected to a control system for data gathering and process control.

We have used the HyClone system to successful scale from 2 to 200 l using CHO cells producing an IgG1 recombinant protein. The HyClone SUB was controlled by a DeltaV-based BioNet system (Broadley James, Irvine, CA). Additionally, a number of customized modifications were made to the standard bag to address shortcomings in the original design, such as extension of the vent filter tube and pressure transducers to reduce foam-outs and avoid bag rupture. Cell culture maintenance, expansion, and process conditions were similar to those described in Section 7.5.2. The initial cell culture process conditions for the production stage were 37°C with a pH of 7 and shifted lower to 33°C and a pH of 6.8 on day 2. The 2-l bioreactor (Applikon, Foster City, CA) was operated at process conditions similar to those of the HyClone system. Samples were taken for cell growth, viability, osmolality, metabolites, titer, and product quality attributes (data not shown) analysis. Excellent scale equivalency was obtained.

### 7.5.4 Future Prospects

All approved mAbs are produced in mammalian cells such as CHO, mouse myeloma (NSO), baby hamster kidney (BHK), human embryonic kidney (HEK-293), and PER.C6 (Section 7.2). Secreted antibodies from these cell lines are glycoslylated in a similar, but not identical, way to their human counterparts. The glycan structures in mAbs can influence their interaction with immune natural killer cells that bind to the constant region (Fc) and destroy antibody targeted cells. This process known as antibody-dependent cell toxicity (ADCC) depends on a specific *N*-glycosylation site at Asn 297 in the Fc domain of the heavy chain of IgG1s [72]. In addition to glycoform structure, the lack of fucose or presence of *N*-acetylglucosamine can impact ADCC potency. Although many mAbs do not exhibit ADCC activity, glycosylation is difficult to control precisely in mammalian cells and may be dependent on a variety of factors such as clonal variations, media, and culture conditions.

Recently, several alternative expression systems such as *Pichiapastoris* and *Escherichia coli* have emerged as promising hosts for mAb secretion when it may be possible engineer specific antibodies [73]. Researchers at Glycofi (a subsidiary of Merck & Co. Inc., Whitehouse Station, NJ) have successfully demonstrated the feasibility of glycol-engineered *P. pastoris* cell lines to produce mAbs with highly specific glycoforms [74]. Several different glycoforms of commercially available rituximab (manufactured as Rituxan by Genentech Inc., CA) were generated, and binding to Fcγ receptors and ADCC activity were measured. This study demonstrated a 10-fold increase in binding affinity as well as enhanced ADCC activity with the glycan-engineered proteins compared with Rituxan. Thus, controlling the glycan composition and structure of IgGs appears to be a promising method for improving the efficacy of therapeutic mAbs when ADCC activity is deemed important. Coupled with the use of well-established *P. pastoris* as a platform, including high cell density cultures, scalability, cost effectiveness, and existing large-scale fermentation capacity, can allow for the high-fidelity production of human glycosylated therapeutic proteins.

*E. coli* has been most commonly used for the production of antibody fragments such as Fabs when Fc-mediated effector functions are not required or deleterious [73]. Simmons et al. [75] demonstrated that efficient secretion of heavy and light chains in a favorable ratio resulted in the high-level expression and assembly of full-length IgGs in the *E. coli* periplasm. The technology described offers a rapid and potentially inexpensive method for the production of full-length aglycosylated therapeutic antibodies when ADCC function is not required. Mazor et al. [76] also showed that it was possible to obtain full-length antibodies from combinatorial libraries expressed in *E. coli*. The full-length secreted heavy and light chains assembled into aglycosylated IgGs which were captured by a Fc-binding protein located on the inner membrane. Flow cytometry was used after permeabilization of the membrane and attachment of the antibody to a fluorescent antigen. The use of cell-free protein synthesis for recombinant protein production is also emerging as an important technology. There are also reports of using *Aspergillus niger* for the production of mAbs or antibody fragments [77]. These authors used *N*-terminal fusion to glucoamylase for both heavy and light chains to express a

full length IgG. Goerke and Swartz [78] recently demonstrated the utility of this technology using *E. coli* cell extracts to produce a number of proteins, antibody fragments and vaccine fusion proteins, with correct folding and presence of disulfide bonds.

The past two decades have seen significant advances in cell culture technology that have increased the expression of recombinant proteins from 100 mg/l to several g/l concentrations. These advances have resulted from intensive research in cell line engineering (vector improvements, high-throughput screening methods for high-producer clones, and introduction of antiapoptotic genes in cell lines to prolong culture viability), media development, feeding strategies, cell metabolism, and better process understanding and their impact on product quality and scale-up studies. Further increases in titers will result from a combination of the above. In particular, improvements in media, including the development of high-yielding chemically defined media with replacement of hydrosylates with specific peptides, is an important area for further work [79,80].

Current fed-batch technology typically does not yield bioreactor cultures in excess of 10% packed cell volume. In contrast in microbial and fungal fed-batch cultures, the packed cell volume can be as high as 30 to 40% of the total bioreactor volume and therefore presents an opportunity to target further increases in cell concentration. Application of robust online sensors (e.g., capacitance sensors and NIR) for cell stoichiometric–based online feeding strategies with lower byproduct formation can be used achieving higher cell density cultures. However, prolongation of culture viability is also required. Better understanding of cell biology, including the application of gene expression analysis using CHO chips and genomic-scale models, will also be key [81,82]. The factors contributing to optimal producer cell lines are often complex and not simply due to one gene, which necessitates an understanding of system-wide properties for better engineering of cell lines [83]. Advances in genomics, proteomics, and metabolomics will fuel these advances; current application of these technologies is still in its infancy. A complete genomic scale-model requires the full annotated gene sequences of CHO cells, and this is currently unavailable. As a result, gene expression study by cross-species hybridization using human or mouse DNA microarrays is an option [84], although it is not very reliable. Researchers at the University of Minnesota BTI, National University Singapore, in collaboration with a consortium have made significant progress in CHO transcript sequencing by developing a CHO cDNA array and mouse oligonucleotide array for examining gene expression during apoptosis in fed-batch cultures. Information from such studies can be used for targeting apoptosis signaling genes to prolong culture viability. The most common approach for engineering antiapoptotic genes reported in the literature involves the overexpression of Bcl-2 or Bcl-xL to prevent mitochondrial release of cytochrome C into the cytoplasm [85]. Integration of small interfering RNAs (siRNA) into CHO cells to modulate gene expression is also a promising technology that can be used to tailor cell line properties. Kim and Lee [86] used siRNA to downregulate lactate dehydrogenase for reduced lactic acid formation in CHO cells.

Another area of research has focused on the use of inducible expression systems in mammalian cells. This strategy has the advantage of decoupling cell growth from product formation. Growth arrest in NS0 cultures via the inducible expression of p21 was reported to result in a significant increase in cell-specific productivity [87]. Current practice for the selection of high-producing clones involves a time-consuming and laborious screening strategy because the random integration of the transgene of interest gives rise to very different expression levels because of the variation in the chromosomal surroundings or because of unpredictable cross-interactions of multiple gene copies [88]. Several strategies have been proposed to overcome the negative position effect of random integration. One of the most promising methods is the use of heterologous recombination systems for site-specific gene integration such as the Flp/FRT system from *Saccharomyces cerevisiae* and the Cre-lox system from the bacteriophage P1 in eukaryotic cells. Coroadinha et al. [89] used the Flp/FRT system to target gene insertion into a high-expression chromosomal locus and succeeded in establishing a viral packaging 293 cell line for consistent high-titer virus production. Fukushige and Sauer [90] demonstrated the use of a lox recombination vector to obtain stable transformants with predictable gene expression profiles. The positive selection vector system was designed to directly select Cre-mediated DNA integration at a lox target (using an inactive lox-neo fusion gene) previously placed into the genome of cultured cells. This technique should allow the rapid and efficient exchange of a single copy of the transgene of interest with no change in expression levels.

A prerequisite to the application of this promising technology is the identification of integration sites that lead to high expression. However, it should be possible to investigate the position effects on gene expression using the site-specific DNA integration Flp/FRT and Cre-lox methods. For example, transfection of DHFR-deficient CHO cells with a loxP-GFP fusion and DHFR genes and high-throughput screening via FACS was used to identify transcription active sites [91]. Simultaneous transfection with two expression constructs and selection with two different selective markers as a means to generate highly productive stable CHO cell lines also appears promising (Section 7.2.2). Overall, these methods should result in greater efficiencies in cell line screening for high producers and a further reduction in development timelines.

Integration of high-throughput technologies, online monitoring and control capability, and automation will allow researchers to broaden the experimental design space as well as lower the cost of process development. From an operational perspective, disposable technologies should continue to see widespread adoption because of the advantages discussed earlier (operational simplicity, reduced turnaround time, facility change-over time, lower capital costs, and lower resource requirement).

# Protein and Peptide Purification

BECKLEY K. NFOR, ESTEBAN J. FREYDELL, and MARCEL OTTENS

## 8.1 INTRODUCTION

The increasing demand for therapeutic proteins and peptides has led to a higher market growth potential for these products [1]. Although advances in upstream technology have enabled improved production titers of recombinant proteins and peptides from a few milligrams per liter to several grams per liter [2], their total manufacturing cost remains extremely high, with a significant proportion (50–80%) coming from downstream processing [3–9].

Downstream processing (DSP) deals with the isolation and purification of biological products from complex cell cultures [3,4,8]. The need to purify these products timely, efficiently, economically and to sufficient purity and quantity applies to every large-scale purification process. The extent of purification depends on the end use of the protein or peptide product. Hence, from the DSP point of view, it is important to know the application of the product of interest. Commercially available proteins and peptides can be classified into food and food additives or nutraceuticals, pharmaceuticals or therapeutics, industrial enzymes, and diagnostics. Some examples of proteins in these different categories have been summarized by Ghosh [10]. Therapeutic proteins and peptides destined for administration by injection generally have the most stringent quality and safety requirements compared with the other categories of products [11,12]. Table 8.1 shows the typical specifications for therapeutic protein products such as monoclonal antibodies (mAbs) [11].

Irrespective of the product application, the general structure of DSP is the same for cell-derived proteins and peptides. The objective of this chapter is to present a comprehensive overview of the key aspects of DSP development of proteins and peptides. The chapter opens with a general description of the DSP steps and highlights their objectives and the basic bioseparation techniques used (Section 8.2). After introducing the general aspects of DSP, recent developments in inclusion body (IB) refolding are presented (Sections 8.3). There are several challenges facing

**TABLE 8.1 Typical Specifications for Therapeutic Proteins [11]**

| Product Specification | Typical Range |
|---|---|
| Purity | >99% |
| Host cell protein | <10 ng/dose |
| Nucleic acid | <10 pg/dose |
| Endotoxins | <1 EU/kg body wt |
| Virus | >12 log reduction |
| Cells | Not detectable |
| Leachables | <10 ppm |

EU: endotoxin units.

DSP development, as outlined in Section 8.4. Section 8.5 reviews strategies for protein and peptide purification process development and how each tries to address or overcome the DSP challenges. Finally, expert views on future directions of purification process development efforts are presented (Section 8.6). An extensive list of carefully selected literature on various aspects of DSP development is also included for further reading.

## 8.2 OVERVIEW OF DOWNSTREAM PROCESSING

Recombinant DNA technology has permitted the large-scale production of almost any biological product via the fermentation route using any suitable expression system (e.g., bacterial cells, yeasts, mammalian cells, insect cells). Depending on the expression system used or the localization of the product (intracellular or extracellular), the material leaving the bioreactor or the fermentation broth may contain the target protein in a complex mixture of cells, cell debris, host cell proteins, nucleic acids, endotoxins, viruses, and other contaminants (e.g., unconsumed media components), which must be cleared or reduced to acceptable levels during DSP (see Table 8.1). Otherwise the product is unlikely to make it through clinical trials and into the market. DSP of cell-derived proteins and peptides is broadly divided into different stages: primary recovery and clarification, IB processing, protease inactivation or nucleic acid removal, concentration or preconditioning, purification, virus reduction, and product formulation or storage, each of which may involve one or more process steps with distinct objectives as depicted in Figure 8.1 and outlined Table 8.2. Separation units and reagents commonly used for different DSP steps are also presented in Table 8.2. The unit operations exploit physicochemical or thermodynamic property differences between the target molecule and impurities to achieve separation [13–15]. This section provides a comprehensive overview of DSP, highlighting the separation techniques commonly used at the industrial scale. More in-depth description of the

**FIGURE 8.1** Generalized block scheme of downstream processing. *Dotted boxes* show the steps that may or may not be present depending on expression system used and the target product localization and chemistry. IB: inclusion body; NA: nucleic acid.

downstream unit operations and their implication for DSP can be found in several dedicated monographs [16–20] and reviews [13,21–23].

### 8.2.1 Primary Recovery or Clarification

The main objectives of the primary recovery or clarification steps are to release the target product from the cells (for intracellular products only) and to remove cells and cell debris from the process stream containing the target product. Intracellular product release is accomplished by harvesting and disrupting the cells before cell and

**TABLE 8.2 Principal Steps and Unit Operations Used in Downstream Processing of Proteins and Peptides**

| Steps | | Objectives | Suitable Techniques or Reagents |
|---|---|---|---|
| Primary recovery or clarification | Cell harvesting | Harvest cells from fermentation broth (intracellular products only) | • Centrifugation<br>• Microfiltration (rotary vacuum filtration, cross-flow filtration, depth filtration) |
| | Cell disruption | Release of intracellular products and byproducts | • Homogenization<br>• Bead milling<br>• Osmotic shock<br>• Chemical or enzymatic permeabilization or lysis |
| | Cell (debris) removal | Separate cells or cell debris from intra- or extracellular fluid containing the product and byproducts | • Centrifugation<br>• Microfiltration (rotary vacuum filtration, cross-flow filtration, depth filtration) |
| Protease inactivation and nucleic acid removal | Protease inactivation | Inactivate or inhibit protease action through binding to the protease | • Serine protease inhibitors (phenylmethylsulfonyl fluoride PMSF, 4-aminophenylmethylsulfonyl fluoride–APMSF, benzamidine HCl, leupeptin)<br>• Cysteine protease inhibitors (leupeptin, chymostatin, antipain HCl)<br>• Aspartic protease inhibitor (Pepstatin)<br>• Metalloprotease inhibitors (EDTA, EGTA) |
| | Nucleic acid removal | Reduce viscosity by removing or reducing nucleic acids | • Precipitation using polyethyleneimine, $MgCl_2$, or streptomycin sulfate<br>• Nuclease enzyme addition (e.g., DNase, RNase) |
| Concentration and preconditioning | Concentration | Concentrate the target protein or peptide | • UF<br>• (Salt-induced) precipitation<br>• Crystallization<br>• (Aqueous two-phase) extraction |
| | Preconditioning | Buffer exchange or salt removal | • DF |

| | | | |
|---|---|---|---|
| IB processing | IB washing | Remove contaminants that adsorb onto IBs | • Detergents: Triton X-100 (0.1–4% v/v) + high salt + EDTA, sodium deoxycholate (2% w/v), sarkosyl<br>• Chaotrophs: 0.5–1 M guanidine HCl or urea |
| | IB harvesting | Separate IBs from wash solution | • Centrifugation |
| | IB solubilization | Denature and solubilize IBs | • Chaotrophs: 8-M urea, 4–6 M guanidine HCl<br>• Detergents: SDS (0.5–2%)<br>• Reducing agents: Dithiothreitol or β-mercaptoethanol (5–100 mM) |
| | IB refolding | Remove denaturants and thiol reagents and allow protein to refold | • Dilution (batch, fed batch or continuous)<br>• Membranes (e.g., dialysis, diafiltration)<br>• Fixed-bed chromatography (ion-exchange, hydrophobic interaction, size-exclusion, or gel filtration)<br>• SMB chromatography<br>• Reverse micelles<br>• Refolding aids: Chaperones, foldases |
| | Chemical and enzymatic treatment | Cut off tag or fusion (poly)peptide to restore protein or enzyme activity or for posttranslational modification (e.g., glycosylation) | • Chemical: citraconic anhydrate (for reversible blocking of lysine side chains)<br>• Enzymes: trypsin, carboxypeptidase B, protease V8 |
| Purification | Product capture | Capture and purify the target product and reduce the process volume as much as possible | • Fixed-bed chromatography (affinity, mixed mode, ion-exchange, hydrophobic interaction)<br>• Membrane chromatography<br>• EBA chromatography<br>• SMB chromatography<br>• ATPS |

(*continued*)

**TABLE 8.2** (*Continued*)

| Steps | | Objectives | Suitable Techniques or Reagents |
|---|---|---|---|
| | | | • UF or DF (mainly for interstage conditioning) |
| | Intermediate purification | Further removal of host cell proteins, nucleic acids, and endotoxins while achieving some virus clearance | • Fixed-bed chromatography (affinity, mixed mode, ion-exchange, hydrophobic interaction, size-exclusion, or gel filtration) |
| | Polishing | Remove product-related impurities such as product aggregates, fragments, and variants | • Membrane chromatography<br>• SMB chromatography<br>• UF or DF (mainly for interstage conditioning) |
| Virus reduction | | Inactivate and clear or reduce viruses to acceptable levels | • Virus inactivation (low pH or 60% EtOH)<br>• Virus retention (nano)filters |
| Product formulation and storage | Product formulation | Formulate the target protein or peptide into the correct dosage form based on the route of administration | • Crystallization<br>• Drying (spray, freeze, tray, fluid bed, drum) |
| | Product storage | Use storage conditions or product forms that ensure long-term stability and storage of the active protein or peptide product | • Granulation, tableting, packaging<br>• Pegylation |

APMSF: 4-aminophenylmethylsulfonyl fluoride; ATPS: aqueous two-phase extraction; DF: diafiltration; EDTA: ethylenediaminetetraacetic acid; EGTA: ethylene glycol tetraacetic acid; EtOH: ethanol; IB: inclusion body; SDS: sodium dodecyl sulfate; SMB: simulated moving bed; UF: ultrafiltration.

cell debris removal as depicted in Figure 8.1. Techniques commonly used for cell disruption can be classified as mechanical (bead milling, high-pressure homogenization) and nonmechanical (e.g., enzymatic or chemical lysis or permeabilization). The nonmechanical methods are more suitable for periplasmic products [24]. Enzymatic or chemical lysis may be used in combination with a mechanical disruption method to improve protein release. When mechanical disruption is used, there is an inevitable release of other cellular components such as proteases, nucleic acids, endotoxins, and other protein impurities, thereby complicating further DSP. Unit operations commonly used for harvesting or removal of cells (cell debris) include microfiltration (cross-flow microfiltration, depth filtration, rotary vacuum filtration) and centrifugation. Early efforts on primary recovery were typically centered on microfiltration because of its low capital cost advantage over centrifugation [25]. However, the operational cost of the microfiltration unit may be higher because of membrane fouling that can occur, especially at high cell densities, which increases the cartridge replacement frequency. With the advent of low shear centrifuges, centrifugation is now commonly used industrially for high-density cell cultures with disk-stack centrifuge being the most widely used [26]. On the other hand, for removal of small debris ($<0.5\,\mu m$), centrifugation is not adequate because of the large g-force or energy input required [18]. For primary recovery of recombinant therapeutic proteins such as mAbs from mammalian cell cultures, a hybrid disk-stack centrifugation–(depth) filtration system has become the industry standard [3,4,27].

### 8.2.2 Protease Inactivation and Nucleic Acid Removal

The presence of proteases in the product stream may lead to proteolytic degradation of the target protein. Hence, proteases must be inactivated or removed from the product stream as quickly as possible. Protease removal is achieved in the chromatographic purification steps further downstream. However, the addition of protease inhibitors to cell lysis buffers may be required to stop the protease activity before their removal. Protease inhibitors are biological or chemical compounds that function by reversibly or irreversibly binding to the protease [28]. Because proteases generally belong to one of four evolutionarily distinct enzyme families (i.e., serine proteases, cysteine proteases, carboxyl and aspartyl proteases, and metalloproteases) with different functional groups and cleavage sites on a protein [19], a "cocktail" of different inhibitors may be required to protect proteins from proteolysis (see Table 8.2) [28,29]. Therefore, when possible, the addition of protease inhibitors should be avoided because these chemicals would have to be removed, further complicating the DSP.

High nucleic acid content increases viscosity. As a general rule, if the viscosity of the clarified liquid stream is higher than 4 cP, then viscosity reduction is required [11]. Nucleic acids and endotoxins are negatively charged macromolecules; hence, their removal can be achieved by using cationic precipitants such as polyethyleneimine (a long chain cationic polymer with a molecular mass of $\sim$24 kDa) [11,20]. Alternatively, a nuclease enzyme (e.g., DNase or RNase) may be added to hydrolyze

the nucleic acids [29]. Other techniques such as anion exchange chromatography (AEX) may also be used. However, because of the relatively high liquid viscosity and the sensitivity of chromatographic techniques to fouling, they are seldom used at this stage. Further removal of nucleic acids or endotoxins (or both) is achieved in the purification steps.

### 8.2.3 Concentration and Preconditioning

The clarified liquid stream leaving the primary recovery section is virtually free of particulate matter and may be obtained as a dilute or concentrated solution of the target protein in a complex mixture of impurities. If present as a dilute protein solution, this stream may need to be concentrated before the purification steps. Otherwise, it is directly sent to the purification steps after preconditioning. The goal of the concentration step is to reduce the process volume and hence the sizes of purification units further downstream. The only real limits to the desirable level of protein concentration are the liquid viscosity and the tendency for proteins to aggregate or precipitate. Ultrafiltration and precipitation are two widely used concentration techniques [19,20]. Aqueous two-phase extraction (ATPS) may also be used, although this is not a routine industrial practice. Direct product crystallization from the clarified liquid stream also sounds attractive but is not suitable at this stage because of the complexity of the process stream. When product concentration is achieved by (salt-induced) precipitation, the precipitate needs to be resolubilized in a suitable buffer.

The preconditioning step is required to adjust the process stream conditions (e.g., buffer or salt type, pH, conductivity) through buffer exchange or salt removal or addition to levels required by the first purification step further downstream. Techniques used include dialysis and diafiltration, with diafiltration being more suitable at the industrial scale because of the large process volumes [19]. Although buffer exchange can also be accomplished by size-exclusion chromatography (SEC), this technique is seldom used at this stage because of its low loading capacity and significant dilution of the effluent stream.

### 8.2.4 Purification

After primary recovery, concentration, or preconditioning, the clarified liquid stream to the purification section often contains the target protein in a complex mixture of host cell proteins, nucleic acids, endotoxins, viruses, and other host cell impurities. When confronted with such a complex mixture, many different purification routes can be followed to achieve the desired product quality, often involving one or more chromatographic steps because of their noninvasive nature and unparalleled selectivity [29]. One generally seeks to achieve the most efficient purification with the minimum number of steps [29–31]. Protein purification generally consists of at least two main steps, (1) product capture and (2) intermediate purification or polishing, both with defined objectives (see Table 8.2). Fixed-bed chromatography is mostly applied for the different purification steps as outlined in Table 8.2, but alternative unit operations that

may offer better throughput are also gaining importance [32,33]. These include monoliths, ATPS, three-phase partitioning, membrane filtration, crystallization, membrane chromatography, and simulated moving bed (SMB) chromatography. Direct product capture from fermentation broth containing cells or cell debris is also possible. This can be achieved by expanded-bed adsorption (EBA) chromatography based on ion exchange or another interaction mechanism [20,34].

After the chromatographic methods to be applied for a given separation problem have been defined, the selection of a suitable chromatographic resin and operating conditions for each method becomes crucial because it may dictate the success or failure of the purification step for which it is intended and hence of the overall separation. The general requirements of chromatographic resins used for protein purification include high capacity, selectivity, recovery yield, and low backpressure at relatively high linear velocities. For product capture, high-capacity, linear velocity (speed), and selectivity are the most important requirements. Resins used for product polishing must exhibit high selectivity for separation of product-related impurities such as product aggregates, fragments, and variants.

### 8.2.5 Virus Reduction

For biological products derived from animal or plant cells, viral clearance or reduction to acceptable levels may be required (depending on the product application). For therapeutic proteins, it is required by the Food and Drug Administration to have at least two orthogonal steps for virus inactivation and removal. Hence, although some level of viral clearance is achieved in the chromatographic purification steps, one or more additional viral clearance steps may be required for these products. In mAb purification platforms, virus inactivation at low pH and virus removal by filtration are typically used [4,27]. Viral filters can be classified on the basis of pore sizes into retroviral (<50 nm) and parvoviral (<20 nm) grade filters [35]. The filter size and position in the purification train can vary from one product or process to another. Their small pore sizes (especially parvoviral filters) make the filters susceptible to fouling and clogging. Thus, pressurized tanks are commonly used to drive fluid through the filters in preference to the use of pumps [27].

### 8.2.6 Product Formulation and Storage

The main objective of product formulation and storage is to get the protein or peptide product in a form or condition desired for final consumption or for long-term product stability and storage. Common methods used for product formulation and storage are summarized in Table 8.2. Protein formulation and related aspects are comprehensively reviewed elsewhere [36,37]. In general, crystallization would be an ideal storage method because the crystallized product is likely to be very pure and stable. However, finding suitable crystallization conditions for most (therapeutic) proteins is still a challenge [38]. Another alternative is complete dehydration of protein product, preferably using a gentle technique such as freeze drying (or lyophilization) as opposed to direct product drying or freezing, which may result in product

inactivation [19]. For product storage in solution or liquid form, a buffer exchange step (e.g., SEC, dialysis or diafiltration, ultrafiltration) may be necessary to get the desired storage condition. However, because storage conditions may be highly protein product dependent, prior screening for suitable storage conditions is generally required [39]. For some proteins, additives (e.g., salt) may be required for the final application or to improve the stability and shelf life of the product [19]. Finally, protein engineering techniques such as PEGylation may be used to improve protein stability and half-life, enabling extended storage or activity of the PEGylated protein products [40,41].

### 8.2.7 Inclusion Body Processing

Prokaryotes such as the bacteria *Escherichia coli* offer several advantages as expression systems, comprising well-understood molecular genetics, that is, the genome can be readily modified, relatively inexpensive culturing procedures, and high fermentation yields [42–44]. One important limitation of these expression systems is that they lack an excretory mechanism; hence, overexpression of certain gene sequences often results in the intracellular accumulation of the product in an inactive, insoluble aggregate known as IBs. If the target protein is present as IBs, these need to be solubilized and refolded after cell debris removal (Fig. 8.1) [45–48]. Chemical and enzymatic treatment may be required after protein refolding to remove tags or fusion polypeptides, which may otherwise reduce the protein activity, or for posttranslational modifications (e.g., glycosylation) of the recombinant protein product. The IB washing step is used to remove cellular contaminants that adsorb onto the hydrophobic IB surfaces. Typical IB washing reagents are shown in Table 8.2. The nonionic detergent Triton X-100 is the most commonly used [49]. Harvesting of IBs (size $\sim$1 mm) from the wash solution can be accomplished by centrifugation. Thereafter, solubilization is typically attained using a solution comprising chaotropes (e.g., urea, guanidine hydrochloride), reducing agents (e.g., β-mercaptoethanol, dithiothreitol), and alkaline pH. This solution breaks the intermolecular interactions in the aggregated protein, freeing the monomer in a denatured and reduced (D&R) form. Ideal solubilization conditions should result in maximum protein solubility, decreasing the fraction of soluble aggregates formed and increasing the fraction of soluble monomer [45,50–52]. Decreasing the concentration of chaotropes and reducing agents in the protein solution initiates refolding, meaning the soluble protein refolds and forms its disulfide bridges. The change in chemical composition is a buffer exchange that can be realized by performing direct dilution (e.g., continuous stirred tank dilution, batch dilution, fed-batch dilution), membranes (e.g., dialysis, diafiltration), or by liquid chromatography (chromatographic refolding). These methods belong to the class of chemical-induced refolding, discussed in more detail later. A separate class is the so-called pressure-induced refolding, not discussed in this chapter. This method employs hydrostatic pressures in the range of 150 to 200 MPa to disrupt aggregated protein, favoring the formation of the native product [53–59].

## 8.3 PROTEIN REFOLDING METHODS

### 8.3.1 Dilution Refolding

Dilution refolding is the most widely used method to refold proteins at an industrial scale because it is considered the simplest way to initiate protein refolding. This approach consists of diluting the denatured, often D&R, protein IB solution with refolding buffer at dilution factors of 50% or higher. This buffer generally does not contain denaturant agents or reducing agents, but it would most likely contain refolding additives (e.g., aggregation suppressors, redox couples) [60]. Protein refolding is initiated as a result of the instant decrease in the concentration of the denaturant and reducing agent. The refolding yield, defined as the amount of native protein per amount of D&R protein loaded, is negatively correlated to the concentration of D&R protein in the refolding reactor [61]. This implies that refolding at high protein concentrations generally leads to a low refolding yield. This correlation is explained by the kinetics of protein refolding and protein aggregation and their dependence on the concentration of D&R protein [61]. Protein refolding is a monomolecular reaction; thus, its reaction rate is linearly dependent on the D&R protein concentration. Conversely, aggregation is a multimolecular reaction; hence, its reaction rate is a power function of the D&R protein concentration [62]. To minimize the product mass loss (improving refolding yield) toward the competing aggregation reaction, batch dilution refolding is usually operated at a total protein concentration between 0.01 and 0.2 mg/ml [61]. This concentration range can be increased by adding additives that mitigate protein aggregation [60,63,64]. In terms of reactor configuration, dilution refolding can be done in a batch [61], fed-batch [65,66], or continuous stirred tank reactor (CSTR) [67]. Based on reactor design theory, a batch reactor is not suitable to maximize yield (conversion) when the product is formed via a first-order reaction competing with a higher order reaction (folding vs. aggregation). Fed-batch refolding (also known as pulse renaturation) addresses this limitation by controlling the rate of D&R protein addition, minimizing the aggregation reaction rate [64,66,68]. Finally, to improve throughput, dilution refolding can be perform on a CSTR [68], or a CSTR in conjunction with fed-batch addition of the D&R protein solution [66]. Fed-batch refolding and CSTR refolding may be operated such that the native product can be concentrated during the refolding operation, which is not feasible using batch dilution refolding alone.

### 8.3.2 Chromatographic Protein Refolding

Refolding using liquid chromatography delivers a relatively high degree of process intensification compared to refolding by dilution. Process intensification encompasses the options of performing (a) protein refolding, (b) change in chemical composition using gradients, (c) purification on the product, and (d) its concentration in one unit operation. Refolding by chromatography has effectively been shown for hydrophobic interaction chromatography [69–71], size-exclusion chromatography

[72,73], immobilized metal affinity chromatography (IMAC) [74,75], and ion-exchange chromatography [76–78]. This section addresses IEX and SEC because most of the recently published literature promotes these two approaches as the ones that could find application at a preparative scale.

***8.3.2.1 Refolding by Ion-Exchange Chromatography*** Ion-exchange refolding (IExR) was first described by Creighton [78]. He showed that a protein denatured using urea could be bound reversibly to an ion-exchange media. Moreover, he showed that urea could be eliminated using a gradient without eluting the bound protein, resulting in refolding and formation of disulfide bridges. Finally, using a salt gradient, the refolded protein could be eluted, obtaining it in a relatively pure fraction, free of urea. Throughout the years, the scientific community gained interest in IExR plausibly because (a) IEX is broadly employed as a purification step in the biopharmaceutical industry, and thus it could be readily introduced in existing processes; (b) compared to SEC, ion exchange has a high loading capacity and the product can be concentrated during elution using a salt gradient; (c) compared to HIC, the protein denatured using urea can be bound to the IEX media using a much lower salt concentration, not the case for HIC refolding; and (d) protein–protein interactions could plausibly be reduced by the spatial separation obtained upon the binding of the protein to the IEX media, presumably leading to less protein aggregation, increasing the refolding yield. Creighton's method has been throughout the years modified to include a simultaneous pH, urea, and salt gradient. This approach has been tested with lysozyme on a cation exchanger [79,80] and iron superoxide dismutase (Fe-SOD) on an anion exchanger [81]. Recently, IExR employing an incubation period at no flow has effectively been used to refold bovine serum albumin [76] and α-fetoprotein [82]. The latter application demonstrated that IExR can be used to refold complex proteins, as in the latter two examples proteins having 16 and 17 disulfide bridges were successfully refolded. Examples of proteins that have been refolded using IEX are presented in Table 8.3. Table 8.3 also presents the operational factors reported and their corresponding values. Refolding yield in this unit operation is influenced by the protein load, the speed of denaturant removal, the adsorbent's backbone type, and the resident time [76,80,83].

***8.3.2.2 Refolding by Size-Exclusion Chromatography*** Refolding by size exclusion was first reported in the work of Werner et al. and afterwards by other groups [73,88,89]. Essentially, the principle of SEC refolding can be described as follows. A pulse containing a denaturant, a reducing agent, and the protein is loaded to the SEC column, already equilibrated using the refolding buffer. Due to the differences in average distribution coefficients, the denaturant, reducing agent, and the protein concentration fronts separate as they progress down the column. This separation results in a decrease in the concentration around the protein of the denaturant and reducing agent, resulting in refolding and the formation of disulfide bridges. Various examples of SEC refolded proteins are presented in Table 8.4.

Refolding using SEC has been done using protein feed concentrations in the range of 0.5 mg/ml [90] all the way to 80 mg/ml [73]. Furthermore, refolding using SEC has been studied using various model proteins and several types of size-exclusion media [91]. In the studies performed, the objective shared was the optimization of the refolding yield. Several approaches have been tested comprising the effect of the type of gel filtration media [92,93], the impact of using a urea gradient and/or a pH gradient [94,95], and the effect of using a chaperone system [96]. Though these strategies could potentially increase the refolding yield, they should not have a substantial impact on specific eluent consumption, volumetric productivity, and final product concentration, as these process performance indicators depend primarily on the mode of operation (i.e., batch vs. continuous).

Batch SEC refolding has the same known limitations of the standard batch SEC purification step. These limitations comprise the use of long columns and a significant product dilution, due to the large column volume to loading volume ratio. The aforementioned limitations result in the need for a large inventory of SEC media, long process times, and a large consumption of eluent(s). These limitations can be offset by changing the mode of operation from batch to continuous. Continuous size-exclusion refolding has been shown on preparative annular chromatography (P-CAC) for α-lactalbumin [97] and lysozyme [98] and simulated moving bed chromatography for lysozyme and an industrial fusion protein [72,99,100].

### 8.3.3 Refolding by Membranes

Membrane refolding can be accomplished using dialysis or diafiltration [101,106–108]. Dialysis is a relatively slow process because the mass transfer–driving force is diffusion. Conversely, diafiltration is a faster process that offers better controllability because the permeate, retentate, and refolding buffer flow rates can be accurately controlled. Furthermore, diafiltration can be operated in a continuous manner, which translates into relatively high volumetric productivities, and could also be used to concentrate the final (native) product. Refolding yields in these systems can be adversely affected by (1) the unspecific binding of the protein to the filtration membrane; (2) losses of protein through the membrane; and (3) concentration polarization, leading to membrane fouling and protein aggregation [49].

## 8.4 CHALLENGES IN PURIFICATION

The purification of proteins and peptides from crude biological cell cultures poses several challenges. To begin with, the product may be present in soluble form or as insoluble IBs, which have to be resolubilized and renatured or refolded. Although IB harvesting from the clarified cell extract may be easy to accomplish, IB refolding poses a significant challenge, with low overall refolding yields and significant product losses [45]. In the soluble form, the products are often present

at very low concentrations in a complex mixture of other impurities, which are ill defined with respect to the composition and the physicochemical (e.g., molecular mass or size, charge, hydrophobicity) and thermodynamic (e.g., solubility) properties of the mixture components, as well as the flow characteristics (e.g., viscosity). This fact renders purification process development and especially the removal of product-related impurities such as other protein isoforms, fragments, and aggregates with similar physicochemical properties to the target molecule particularly challenging [30]. Furthermore, it is important to distinguish between impurities that may be tolerated and the so-called "critical impurities" or "critical contaminants" that must be removed as soon as possible (e.g., proteases that may degrade the target protein). Moreover, most protein products are thermolabile and are sensitive to extreme pH and to chemical substances such as surfactants and organic solvents. On the process perspective, there may be several bioseparation unit operations to choose from at each processing step, each of which may have several process parameters and operating conditions to be optimized, giving rise to an optimization problem. This is further complicated by the large number of possible interconnections of the unit operations into candidate process flowsheets, leading to a combinatorial problem in the process synthesis, and the fact that many bioprocess unit operations operate in batch or semi-continuous mode and require regular cleaning. Finally, therapeutic proteins and peptides must not only meet stringent product quality and safety requirements by regulatory agencies (e.g., product purity and biological activity and the permitted levels of host cell proteins, nucleic acids, endotoxins, and viruses), but their time to market also needs to be as short as possible [4].

## 8.5 PURIFICATION STRATEGIES

Despite the technical challenges, the short time to market for cell culture–derived therapeutic products means that their purification process development must be performed timely, and the products must satisfy the strict product requirements by regulatory authorities. Strategies for protein and peptide purification process development can be broadly classified into the heuristics or expert knowledge–based method, high-throughput experimentation (HTE), platform strategies, algorithmic- or optimization-based methods, and hybrid methods involving a combination of strategies [1,30,109].

### 8.5.1 Heuristics or Expert Knowledge–Based Method

Before the advent of HTE, purification process development was mostly performed traditionally (i.e., using a set of heuristics or rules of thumb based on past experience, supported by some laboratory-scale experiments). Because of the time and material cost of performing experiments at the laboratory scale, heuristics are first used to synthesize one or a few candidate purification processes for a target product [18,110,111] followed by laboratory-scale testing to find a working process and

suitable operating conditions, mainly on the basis of trial and error, and finally by the scale up of any working process as long as it satisfies the customer and regulatory needs. This purely traditional approach often results in overall suboptimal processes with inefficient feedstock and auxiliary materials utilization and high DSP costs. There have been attempts to capture expert knowledge on the computer in the form of expert systems [14,31,112–115] supported by physicochemical properties characterization of the target protein and major protein contaminants [116].

### 8.5.2 High-Throughput Experimentation

Nowadays, the use of heuristics for initial process screening has been largely replaced by high-throughput process development (HTPD, i.e., involving the use of HTE) [117]. Although the general protein purification guidelines are still very useful, chromatographic resin screening and the optimization of buffers and operating conditions are now largely performed by high-throughput screening (HTS) using 96-well plate format and robotic liquid handling technology [118,119]. HTS of chromatographic resins enables the exploration of a much wider space of process variables than possible with conventional column experiments because of miniaturization and parallelization of experiments, with significant savings in time and material costs [118–127]. Data obtained by HTS of chromatographic resins are very useful for fast resin and process evaluation during the early stages of process development [118,123–125,127–131].

The major biopharmaceutical companies have adopted a more structured HTPD approach involving the combined use of high-throughput resin screening followed by column scouting and optimization and scale up of the optimized process showing the best performance [132]. The main idea is to first reduce the large experimental space as cheaply and as fast as possible by means of HTS and then focus the column-scouting experiments on the most promising resin options only. With the availability of miniaturized column formats, it is now possible to perform scouting experiments also at high throughput [127,131].

A good overview of commercially available tools for HTPD can be found in Bhambure et al. [117]. The major challenge of using HTS is in the handling and analysis of the large amount of experimental data generated, for which better techniques and tools are needed. Combined with statistical design of experiments or evolutionary search algorithms, however, an optimal system can be reached in which the number of experiments performed in HTS mode is minimized while maximizing information gained from the data [125]. This approach even allows the optimization of unit operations when no physical model exists and process knowledge is minimal.

### 8.5.3 Platform Strategies

After an economically viable purification process has been developed for a given protein product by HTPD or otherwise, this might serve as a platform or template for other products within the same category, such that purification schemes for the

different proteins in that category show a high degree of commonality [4,27]. For example, the purification platforms for most mAbs contain at least two chromatographic steps, including a protein A affinity chromatography capture step, two or more chromatographic polishing steps, and at least two orthogonal virus removal steps to ensure product safety [3,4,27,133]. Platform approaches for mAb purification are mainly driven by the projected large increase in the number of antibody therapies and time-to-market considerations [4,8,27].

The advantages of using a platform approach include savings in time and effort and greater harmonization of practices and information across different functions and sites within a biotech organization [4,27]. Optimization mainly involves improvements of individual steps because the purification cascade is more or less fixed. In the case of the mAb purification platforms, for example, optimization efforts have been focused on improving the dynamic binding capacity of the protein A affinity step from the current range of 30 to 50 g/l to 80 to 100 g/l [3,4], as well as on designing new-affinity ligands [6]. There have also been attempts to replace or eliminate at least one of the conventional IEX steps in the mAb process. In this regard, the potential of membrane IEX as a replacement of the flow-through mode anion exchange chromatographic step for removal of low-level impurities such as host cell proteins and DNA has been demonstrated [134,135].

### 8.5.4 Algorithmic or Model-Based Methods

The algorithmic methods of process development involve the use of mathematical models and computer simulations to predict, optimize, and scale up a purification process [1,30,136], as well as for robustness studies to ensure consistent process performance [137–139]. In this way, the number of experiments is kept to a minimum. This has been made possible through the development of reliable state-of-the-art unit operation models and sophisticated computer programs to assist in DSP development [16,140,141]. Key aspects in the model-based approach include the development of suitable analytic procedures for model parameters acquisition and model validation [136].

Despite the potential benefits, model-aided process development based on sound thermodynamic property data is still lagging behind in the biopharmaceutical industry because of a variety of reasons: (1) the complex and ill-defined nature of typical bioprocess feed materials, (2) the lack of suitable analytical tools and methods to deal with these and the time and material costs that may be involved, and (3) other practical considerations such as the large number of variables and auxiliary materials (e.g., resins, buffers, salts) to be screened. This is changing with the advent of HTE, as discussed under the hybrid approach in Section 8.5.5.

### 8.5.5 Hybrid Methods

By definition, a hybrid approach combines two or more different strategies for process development by taking advantage of the strengths of each. Here, we focus on the model-based HTPD approach involving the integrated use of HTE and process

**FIGURE 8.2** Overview of model-based high-throughput protein purification process development approach by Nfor et al. [142]. DoE: design of experiment; HTE: high-throughput experimentation.

modeling for purification process development. In the model-based HTPD strategy, in addition to using HTE for screening auxiliary materials and operating conditions, the latter is also used for fast acquisition of thermodynamic properties data of proteins and proteins assemblies of common host organisms, bringing the possibility of model-based prediction and optimization of fairly complex systems to practical reality.

A typical example of how this concept of model-based HTPD could be applied in practice is provided by Ottens and coworkers [30,142–145], as depicted in Figure 8.2.

In their approach, HTE and modern proteomics tools such as mass spectrometry are used for the fractionation and characterization of crude protein mixtures to obtain the necessary physicochemical and thermodynamic properties of the target protein and the major protein contaminants (i.e., those with close selectivity to the target protein in each defined separation method) needed for process modeling [144,146]. Using the obtained parameters as inputs, a computer algorithm based on properly validated unit operations models is used to find an optimum purification cascade [145]. The selected purification cascade then undergoes further experimental verification, optimization, and robustness analysis using a combination of process modeling, HT and laboratory-scale experiments, and design of experiments tools to identify the critical process parameters and define their operating windows. This is followed by model-assisted, detailed design and economic evaluation of the best process. An important aspect of the modeling framework is that the thermodynamic models or adsorption isotherms used to capture protein–ligand interactions in process chromatography must be reliable. Attempts have been made to establish

generalized mechanistic thermodynamic frameworks that cut across multiple separation mechanisms and methods [13,147,148]. Rational model-based methodologies for fast and rational resin or process evaluation and selection have also been developed [143–145], as well as a multidimensional experimental scheme for fast acquisition of the relevant model parameters [146].

The main characteristics of the process development strategies discussed were recently summarized by Rathore and coworkers [117], and the strengths and weaknesses of each are outlined by Nfor et al. [30].

## 8.6 FUTURE DIRECTIONS

This chapter would be incomplete without probing into future bioseparation process development directions. The discussion here was consciously limited to process development for therapeutic proteins and peptides that show the greatest potential for growth and have the greatest regulatory concerns.

Although purification platforms are currently safely positioned within the biopharmaceutical industry because of the accrued benefits [27], an interesting debate has emerged over the capability of existing purification platforms and facilities to adequately respond to the DSP needs of the future, such as higher capacity and product quality; shorter time to market; and better process monitoring and control [3,5]. Moreover, it has been demonstrated that an inflexible generic platform with fully templated operating conditions is hardly possible because of dramatic differences in elution behavior because of property differences, as observed for mAbs [27]. Hence, some biopharmaceutical companies (e.g., Amgen) have adopted a flexible generic platform instead in which optimization of the individual process steps is still a must for each mAb [27].

Furthermore, as patent rights on protein therapeutics expire and other manufacturers step into the same or similar product market (the so-called biosimilars market), competition among biosimilars manufacturers will become rife, and so will the need to cut significantly on purification costs, although others have argued that stricter comparability testing for biosimilars may diminish their potential as market drivers [5].

In either case, process development tools and strategies that emphasize better process understanding, monitoring, and control through the quality by design and process analytical technology initiatives are likely to be more responsive to these future needs [1,117,149,150]. In our view, the hybrid method based on a combination of HTPD and process modeling is best suited to meet these challenges.

As demand and throughput requirements on therapeutic proteins and peptides continue to rise, we will probably also see a rising need for better scalable, non–packed-bed chromatographic techniques such as aqueous two-phase systems, selective precipitation with polyelectrolytes or polymers, high-resolution ultrafiltration, crystallization, monoliths, and membrane chromatography [32–34], although packed-bed chromatography will continue to be the workhorse for protein purification for decades to come because of its unparalleled selectivity. Innovations in

packed-bed chromatography will mainly involve the development of better quality adsorbents with better mass transfer characteristics, higher capacity, and less susceptibility to fouling and reuse. EBA chromatography for direct product capture from crude cell cultures will continue to make its (re)entry (e.g., DSM's RHOBUST technology [34]). SMB technology will also gain importance for large biopharmaceuticals as capacity and productivity needs increase. When product expression titers are much higher than impurity levels, simple but innovative solutions such as designing chromatographic ligands for capture operations in flow-through mode could be used instead (i.e., designed to bind impurities) in which case the binding capacity will no longer be considered a bottleneck for increasing the throughput of the capture step because the impurity levels are much lower. Protein engineering strategies for selective protein purification through the use of protein tags (e.g., PEGylation) or through the development of ligands for selective affinity purification of native target proteins will also gain ground [151].

There is increasing pressure within biopharmaceutical companies to minimize extensive investments in new facilities and optimize the usage of existing facilities because of a combination of factors such as the increasing number of drug candidates, the slowing rate of new drug approvals, and increased competition. Hence, effective utilization of manufacturing facilities will become a major driver for process innovation, and innovative technologies that can operate within existing facilities are likely to shape the market landscape [5]. For therapeutic products with small niche markets, for example, high product titers could bring a radical shift toward lower production volumes, which in turn will increase the need for facility flexibility and the use of disposable technologies [5].

With the ever-growing importance of HTE tools such as miniaturized column and well formats and microchips, there is already a growing need for analytical methods that are compatible with these miniaturized systems [131]. We shall also see important developments in microfluidics as the application areas of microchips in biopharmaceutical process development increase (e.g., second viral coefficient or solubility determination on chip for product stability or shelf-life studies [152], ATPS on chip [153], diffusivity measurement on chip [154]).

Only within the past decade or so, there has been significant progress in the way process development in the biopharmaceutical industry is performed, although there are still many challenges to overcome, as highlighted in this chapter. Effective communication among the regulatory bodies, industrial practitioners, and academic researchers is key in addressing the remaining DSP challenges and in bringing to realization, the industrial implementation of new (innovative) DSP technologies.

# Chemical and Genetic Modification

MONIKA FARYS, CLAIRE L. GINN, GEORGE O. BADESCU, KAROLINA PECIAK, ESTERA M. PAWLISZ, HANIEH KHALILI, and STEVE J. BROCCHINI

## 9.1 INTRODUCTION

There are many natural posttranslational modifications (PTMs) of proteins (e.g., glycosylation, ubiquitination, acylation, amino acid derivatization) [1–4]. Glycosylation is common for therapeutic proteins. Classes of proteins modified by glycosylation include monoclonal antibodies (mAbs), blood factors, hematopoietic proteins, and cytokines. Excluding mAbs, many therapeutic proteins were developed as a replacement for a corresponding endogenous protein. Maintaining control of protein structure to be as close as possible to the structure of the endogenous protein has been a key goal.

Second-generation versions of many protein therapeutics involve some type of modification engineered to improve the protein [5,6]. For example, erythropoietin (EPO) [7] has been modified to have two more glycosylation sites (darbepoetin alfa; Aranesp), and EPO has also been covalently conjugated to poly(ethylene glycol) (PEG; methoxy polyethylene glycol-epoetin β; Micera). Broadly, these modifications of EPO were made to increase its circulation half-life.

As medicines, proteins are generally highly selective and potent, but they suffer from substantial limitations that can include the potential to be immunogenic (e.g., formation of antidrug antibodies), physicochemical instabilities (e.g., propensity to aggregate), and suboptimal pharmacokinetics (e.g., rapid clearance). Proteins have not naturally evolved to be produced and purified on a large scale as they are when used as medicines. Production and downstream processing can considerably influence protein homogeneity and physicochemical characteristics.

Proteins have certainly not evolved to be administered and used as medicines. Many endogenous proteins of therapeutic relevance are often regulated at low concentration within the body. Their clinical administration can result in highly fluctuating *in vivo* concentrations that also do not reflect their natural abundance and

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*,
Edited by Shayne C. Gad

biodistribution within the body. In this context, the potential for immunogenicity can increase.

The widespread clinical use of proteins is further complicated by side effects such as an increased susceptibility to infections or malignancies that may develop even after treatment has stopped [8]. Regulatory vigilance has resulted in an increase of postapproval safety-related regulatory actions [9] and some withdrawals (e.g., efalizumab, gemtuzumab, ozogamicin).

Despite these limitations, protein-based medicines are established with more than 174 protein therapeutics in the clinic [10,11]. Many types of modifications are being made to improve the therapeutic properties of proteins. These are becoming increasingly important as lifecycle management leads to biobetter versions of existing medicines and as nonendogenous proteins [12] are being introduced to the clinic. There are many reasons to modify proteins for therapeutic use. This chapter focuses on (1) optimization of protein pharmacokinetics, (2) improvement of protein properties to be used as medicines (this primarily includes reduction of immunogenic sequences and improvement of protein stability), (3) addition of a therapeutic effect, and (4) to use of proteins as diagnostics. Protein fusion methods are only discussed in the context of increasing blood circulation times. There is no effort in this review to discuss the important and highly active field of bispecific antibodies.

Modifications to proteins can be made by both recombinant [3,4] (e.g., protein fusion, structure based engineering, humanization) and chemical conjugation [13–18] (e.g., polymer conjugation, antibody–drug conjugates [ADCs]) approaches. Recombinant approaches include modifying protein structure to remove epitopes that could lead to increased propensity for immunogenic reactions [19,20] and to substitute amino acids that are prone to cause protein aggregation. Protein aggregation is often thought to contribute to immunogenicity [21,22]. Modifications that decrease aggregation and remove obvious epitopes or conformational sources of immunogenicity are therefore important [23]. Therapeutic proteins are large molecules that often exert their mode of action in the blood compartment, but increasingly, they are being used for intracellular targets (i.e., ADCs). Many potential applications for proteins do exist [24,25] and much early preclinical research has been described in the literature; however, this review focuses primarily on research that has at least gone to late preclinical development, and preferably to at least clinical evaluation.

## 9.2 PROTEIN MODIFICATION TO INCREASE CIRCULATION HALF-LIFE

The continued development of protein-based medicines relies on achieving optimal pharmacokinetics in the blood compartment. Although many therapeutic monoclonal antibodies (mAbs) (e.g., $IgG_1$) can display extended half-lives by recycling via interaction with the Fc receptor when a large enough dose is given, other proteins tend to clear rapidly (minutes to a few hours). The frequency for dosing is often increased when a protein rapidly clears from circulation. Although this is inconvenient to the patient and increases the cost of treatment, efficacy may be

compromised because rapid clearance can result in a subtherapeutic plasma concentration between doses. Increased dosing frequency also means the patient will experience side effects more frequently. Optimizing pharmacokinetics is often a key challenge that should be addressed early in preclinical development.

Many strategies have been evaluated to increase the circulation half-life of therapeutic proteins [26,27]. Clinically successful strategies include those based essentially on increasing the size of the protein by conjugation of a flexible water-soluble polymer or by addition of more glycosyl groups onto the protein. This is known as glycoengineering [5,28–32], which is generally accomplished recombinantly, but can also be accomplished by chemical modification strategies [32]. Polymer conjugation has focused primarily around PEGylation [33–39]. Another strategy involving the modification of a protein to prolong its circulation time is to exploit endocytic recycling mechanisms [40–48]. This is most often accomplished clinically by recombinantly fusing the protein of interest to the Fc portion of an immunoglobulin G (IgG). Much work has also been accomplished to fuse albumin or albumin binding proteins to the therapeutic protein of interest. Pumps to prolong dosing into the bloodstream have been successful with smaller polypeptides (e.g., insulin) and less often with proteins, probably because of formulation limitations to maintain protein structure in such conditions. The same can be said of colloidal systems where formulation limitations may also dominate. Although in principle the protein can be introduced to the circulatory system in unmodified form when released from a pump or colloid, the protein will still clear quickly. High flux may be necessary to ensure there is a therapeutic level of protein over the necessary time period required for efficacy.

### 9.2.1 Chemical Conjugation of Water-Soluble Polymers

Rapid clearance *in vivo* as a result of glomerular filtration and proteolytic degradation is a common limitation to the efficacy of many therapeutic proteins. Conjugation of a flexible, water-soluble polymer can increase the circulating half-life of proteins by tackling both of these issues [49,50]. The most common polymer used to modify proteins is PEG. The solution size of a PEG–protein conjugate is generally dominated by the PEG rather than the protein [51–54], and the resulting conjugate can have a hydrodynamic volume 10 times that of the unconjugated protein [52]. This size increase of the protein conjugate can be above the kidney filtration threshold, resulting in a significant extension of the blood circulation time. In addition, the PEG molecules can mask or block the protein surface by steric shielding effects to reduce interactions of the protein from proteolytic enzymes [55]. Increased blood residence time results in reduced dosing frequency because the therapeutic effect can be maintained for longer time periods. Steric shielding effects of the polymer can, in principle, reduce interactions of the protein with the immune system and antigen-presenting cells.

In addition to the limitations posed by their rapid clearance, protein-based medicines are complex molecules prone to aggregation. Protein aggregation can make it difficult to achieve dose reproducibility and is generally thought to increase the risk of immunogenicity. Regulatory agencies enforce stringent criteria for characterizing and minimizing aggregation phenomena in final dosage forms of

protein-based medicines. Because protein-based medicines are administered parenterally, formulation options are limited. Conjugation of a flexible, water-soluble polymer such as PEG can often decrease the susceptibility for a protein to aggregate in solution. Again, steric shielding effects of the conjugated polymer cause a decreased propensity for protein aggregation. Together, the requirements for optimized pharmacokinetics [56] and the need for stable formulations pose challenges that must be addressed when developing protein-based medicines.

Many different polymers have been conjugated to proteins by a wide range of methods [16,57–69] in efforts to extend their circulation half-life [17,39,59–63]. Notable polymers that have been examined in recent years include the degradable polysaccharides; polysialic acid [64–66], which has been conjugated to EPO and is in clinical evaluation; HEPylation (heparosan polymer); and hesylation (hydroxyethyl starch) [59]. In adition to PEG and some of its variants [67], polyoxazoline is a synthetic, nondegradable, flexible water-soluble polymer [68] that has also been examined for protein conjugation.

***9.2.1.1 Protein PEGylation*** Clinically, it is PEG which has been used as a conjugating polymer and it has been conjugated to proteins in at least 11 clinically used products (Table 9.1) [33,38,69] with approximately 20 PEGylated proteins in clinical development [39]. Hence, protein modifications derived from PEG will form the basis of this section.

As with almost any protein therapeutic, there are issues with the manufacture, characterization, and use of PEGylated proteins [70–75], including the potential induction of anti-PEG antibodies [76], especially in the case of hyperPEGylated products that contain large numbers of conjugated PEG molecules [77–78]. Many proteins used as therapeutics display some propensity for immunogenicity [79–84]. While PEG may have the potential to decrease the immunogenicity of the therapeutic protein, there is a risk of secondary antibodies against PEG. One aspect of anti-PEG antibodies may be attributable to the ubiquity of PEG in wide range of health care and consumer products as a contributing cause for anti-PEG antibodies [77,79]. Much work remains to be done to understand what might be the clinical features of any potential immunogenic reaction toward PEG in PEG-modified proteins [85], but it is generally thought that any observed toxicity of a PEG-protein conjugate is due to the protein [86].

The fact is that PEGylated proteins have an enviable track record of safe clinical use and benefit [86]. PEGylation can provide significant unexpected, and still not completely understood, therapeutic benefits [50,87–90]. There is still also much to be learned about how *in vitro* biological properties for PEGylated proteins obtained during preclinical studies correlate to what is observed *in vivo* [87,91] and in the clinic. The steric shielding effects of the polymer that prevent proteolytic degradation can also decrease biological activity, especially when observed using *in vitro* assays. While decreased *in vitro* activity is the norm for PEG-protein conjugates, it is essential that PK/PD data are obtained to determine the potential of preclinical candidates.

Steric shielding tends to decrease the on-rates of the PEG–protein conjugate for receptor binding [59,92–94]. The off rate, though, is often little changed from the

**TABLE 9.1 Clinically Registered Proteins Modified by the Covalent Conjugation of Poly(ethylene glycol)**

| PEGylated Product | Year Approved | Company | Type of Modification | PEG Used | Indication |
|---|---|---|---|---|---|
| PEG–adenosine deaminase (Adagen) | 1990 | Enzon | HyperPEGylation, random | Linear, 5 kDa | SCID |

native protein. Although the site of PEG conjugation on the protein can influence the relative biological activity [95–100], PEGylation does not cause a protein to display a biological function that differs from the native protein [101–103]. Translating preclinical observations of PEG protein efficacy to the clinic must be done using relevant *in vivo* models in which increased circulation can compensate for decreased *in vitro* activities. The key appears to be that the extension of circulation time can result in an extended *in vivo* pharmacologic effect that has been clinically exploited for the different PEG-modified protein products now being used [49–50].

In several cases, the PEGylated protein has become first line treatment. Often the two clinically used PEGylated interferon-α2 (INF-α2) products are cited as definitive examples of how a PEGylated protein has shown real benefit [104]. PEGylated INF-α2 is used to treat hepatitis C, so efficacy can be measured empirically by reduction of the sustained viral load [105–108]. Only with the use of PEG–INF-α2 and ribavirin has it become possible to cure patients of some genotypes of hepatitis C. Although now first-line treatments, there was significant loss of *in vitro* activity observed during preclinical development for both PEGylated INF-α2 products (Pegasys, ∼7%; PEG-Intron, ∼28%) [109]. It is difficult to predict preclinical efficacy based only on observations of *in vitro* activity. Even though the *in vitro* activity is diminished for PEGylated INF-α2, the native protein is very active (∼9 pg/ml $ED_{50}$), which means even a decrease to 1% of the *in vitro* activity for the PEG protein may still be clinically efficacious if half-life can be extended.

Other PEGylated proteins (e.g., EPO, granulocyte colony-stimulating factor [G-CSF]) are also now standard treatments in noninfectious and often chronic conditions. In these examples, PEG modification of a clinically used protein has provided a means to make a biobetter version of the protein. A recently approved PEGylated product is peginesatide (Omontys, approved in 2012), which is a peptide that is PEGylated during solid-phase synthesis [110] and has been developed to treat patients with anemia who have developed pure blood red cell aplasia (PRCA), which can occur from treatment with EPO. While this product was not inferior with either epotin or darpepotin in anemia and chronic kidney disease, respectively, it was recalled in 2013 for safety concerns related to hypersensitivity [111] presumably caused by the therapeutic polypeptide.

Reduced activity *in vitro* accompanied with improved biological activity *in vivo* has also been demonstrated for other PEGylated protein therapeutics such as IL-2 [112], IL-6 [113], and tumor necrosis factor α (TNF-α) [114], for example. It is thought that preclinical development could be accelerated if site-specific PEGylation is easier to accomplish because in some cases, it appears that when PEG is conjugated to the same site on a protein, *in vitro* activity can be broadly maintained as PEG size is changes [115]. However, other studies indicate that PEG shape (morphology), when conjugated to the same site, can influence *in vitro* activity and that ion exchange chromatographic retention can correlate to activity [116].

Also, the possibility exists that if higher potency can be achieved while the protein displays extended circulation times, then lower doses or less frequent dosing schedules may be possible, either of which may be important as a means to minimize side effects over a given course of treatment. The defined incorporation of non-native

amino acids for site-specific conjugation in an optimal location on the protein may provide the option to achieve good potency for a polymer conjugated protein [117]. It has also been hypothesized that selective PEGylation at either termini of a protein might offer the potential to achieve good potency [118].

Although PEG is currently the only polymer used clinically for conjugation to therapeutic proteins for parenteral administration, much research continues to be focused on the development of protein–polymer conjugates using other polymers [59,119,120] and molecules (e.g., lipids). Many strategies used with PEG will also broadly apply to other polymers.

***9.2.1.2 The evolution of protein modification with PEG*** PEGylation was first described by Davis, Abuchowski and Palczuk in the late 1970's and it is generally recognized that there has been little toxicity observed for PEG in the wide range of consumer and health care products in which it is used [86]. PEG is approved by the Food and Drug Administration (FDA) as an excipient that is widely used in pharmaceuticals, including injectable, topical, rectal, and nasal formulations. This lack of toxicity is also generally observed when a PEGylated product is administered parenterally [86,122]. Although some concerns have been noted because of high-dose accumulation in animal models [123], which would be expected for any water-soluble polymer, recent regulatory approvals suggest that parenteral doses of up to 200 mg or more weekly of PEG as part of a PEGylated product are possible for extended periods [86,122,124–127].

In the early 1990s, the first PEGylated protein (PEG–adenosine or Adagen) was approved for the treatment of severe combined immunodeficiency disease (SCID) [128]. PEG–asparaginase (Pegaspargase, Oncaspar, approved in 1994) for acute lymphoblastic leukemia soon followed [129]. These are PEGylated nonhuman bacterial enzymes, and PEGylation allowed these medicines to be used more effectively in the clinic [130]. PEG-asparaginase is produced by hyperconjugation of 5 kDa PEG. The surface of PEG–asparaginase is saturated with PEG molecules (5 kDa). This is known as hyperPEGylation. Recently, PEG–uricase (pegloticase) (see Table 9.1) was approved for clinical use. This porcine-derived PEGylated protein is a tetramer and is used for the treatment of chronic gout. It is hyperPEGylated with 36 ($9 \pm 1$ per subunit) hydroxy PEG (10 kDa) molecules in an effort to reduce clearance by anti-PEG antibodies [131]. HyperPEGylation of uricase protects it from proteolytic enzymes to prolong its half-life and to minimize immunogenicity to uricase so it can be used to treat a chronic condition.

PEGylation has evolved from the initial random hyperPEGylation to monoPEGylation. Many of the current products in the clinic are monoPEGylated with PEG at different sites on the protein. Many of the conjugation strategies used with PEGylation have been used with other polymers. It should be noted, however, that a conjugation moiety on different polymers may have very different reactivity, and purification of the polymer conjugate may vary [132]. For example, purification of polysialylated conjugates will be considerably more anionic than the unconjugated protein. In contrast, PEG conjugates will not have any charge imparted to the conjugate by the PEG because it is a neutral polymer. Hence, purification by ion

exchange chromatography requires very different conditions for conjugates derived from these two polymers.

Typically, the strategy for polymer conjugation is directed toward the nucleophilic amino acid side chains (e.g., lysines, terminal amino group, serine, histidine). Although strategies have been described that result in some degree of selectivity for lysine conjugation [30], conjugation usually occurs at a number of different sites to yield positional conjugation isomers [133,134]. Another approach to vary protein reactivity [135,136] is recombinantly to deplete the number of lysines on the protein surface and replace them with less reactive residues to reduce the number of conjugation sites.

For monoPEGylated proteins where PEG is not selectively conjugated to a specific amino acid residue in the protein, each positional PEG–protein isomer will display different physiochemical, biological, and pharmaceutical properties [137–139]. The same would be expected for any polymer conjugated nonspecifically to a protein. Many of the PEG conjugation reagents (e.g., PEG–*N*-hydroxysuccinimide esters) also tend to undergo competitive hydrolysis reactions with water, which requires large excess of reagent for good conjugation conversion while complicating downstream processing.

Thiol-specific conjugations have been extensively examined to achieve more homogeneous monoPEG protein conjugates. Thiol-based conjugations are often more efficient and site specific than conjugations to other protein nucleophiles (e.g. lysine $\varepsilon$-amino groups). Most therapeutic proteins do not have a free cysteines. If cysteines are present in a therapeutic protein, there is usually an even number of them and they pair up to form protein disulfide bonds. Much work has been described to add a cysteine recombinantly to a protein for PEGylation [140,141]. However, if there is a disulfide present in the protein, these engineered proteins suffer from limitations associated with disulfide scrambling and aggregation. Despite these limitations, the advantages of thiol-specific conjugation were exploited to develop certolizumab pegol, which was approved in 2008. This PEG modified protein is an anti–TNF-$\alpha$ Fab with a free cysteine that has been engineered into its structure for conjugation to a PEG reagent that comprises two PEG molecules of 20 kDa each (total, 40 kDa; often simply called a 40-kDa branched PEG reagent).

Incorporation of a single cysteine is probably most appropriate for site-specific conjugation of proteins that do not have any disulfides. For example, a protein scaffold derived from a fibronectin type III domain that does not have a disulfide in its structure has been engineered to have a free cysteine for PEGylation and is currently in clinical trials [142,143].

Interestingly, many thiol-selective conjugations are conducted with maleimide-based reagents, and recent evidence indicates that these reagents are labile to hydrolysis [144] and can undergo exchange reactions in *vivo* [145]. To address maleimide instability, new thiol-selective reagents have been developed [146].

Another approach is to use conjugation reagents capable of bis-alkylation that can conjugate to both cysteine thiols from an existing disulfide in the protein [147,148]. Conjugation results in a 3-carbon bridge spanning the two cysteine thiols of the

original disulfide with PEG conjugated site-specifically on the bridge. An alternative approach for site-specific conjugation using bis-alkylating reagents is that they can conjugate a protein His-tag site-specifically [118]. Because it is rare to have multiple histidines next to each other in a protein [149,150], it makes the His tag a good target for selective conjugation of the PEG. This strategy offers the potential for site-specific conjugation to be applied to virtually any protein.

In addition to cysteine-specific modification, other amino acids such as arginine [151], glutamic acid [152,153], and even methionine [154] have been targets for site-specific conjugation. Glycosyl moieties have also been described as targets for protein modification [155–157]. PEGylation of either the C- [158,159] or the N-terminus [160–167] of proteins has also been described.

A particularly interesting approach for C-terminal polymer conjugation is to produce intein–fusion proteins that can be cleaved with hydrazine to give a C-terminal hydrazide that can then undergo ligation reactions with a suitable keto substituted polymer [168]. Reductive amination has been extensively investigated for protein N-terminal conjugation [165,169–171], and this process is used for pegfilgrastim (PEG–G-CSF). Imine formation is the first step in reductive amination with water as the byproduct, and so homogeneous imine formation is not generally efficient in terms of reagent stoichiometry or site specificity [170,172]. Efforts have been published to optimize reductive amination to G-CSF [173] and other proteins (e.g. staphylokinase, growth hormone) [170,174] as a means to maximize N-terminal selectivity and conjugation efficiency. The His tag–selective PEGylation mentioned earlier [118] is a potential alternative to C- and N-terminal PEGylation.

Other approaches for site-specific of modification of proteins have been described using enzymes, such as transglutaminase [175], glycosyl-transferases [176], and sortase [177] as well as genetic insertion of unnatural amino acids to enable generation of selectively PEGylated proteins [178–183]. Incorporation of non-native amino acids requires that cellular biochemical pathways probably need to be robustly modified [181,184] to ensure that the efficiency of protein production is not compromised by reversion to the wild-type phenotype.

Nonetheless, non-native amino acids with alkenyl, iodo, and keto moieties for reaction can in principle be incorporated and used for site-specific conjugation. For this strategy to work, tRNAs with the desired codon, usually the amber stop codon, are aminoacylated with the amino acid of interest. The reengineered tRNA is then added into the expression system along with the DNA template. This technique was used to insert an azide group at a specific site in the sequence of superoxide dismutase [178]. In this instance, conjugation with an alkyne terminated PEG yielded conjugates with similar activity to the native enzyme. The use of copper-mediated click reactions can be difficult to achieve with proteins, generally because of excessive purification processes and the sensitivity of proteins to the reaction conditions. Yields of amino acid incorporation can also be poor because of their competition with termination codons. This approach is currently limited to the addition of a single type of non-natural amino acid because only the action of the single amber stop codon can be suppressed.

### 9.2.2 Glycosylation Modifications

Glycosylation is the most common posttranslational modification of proteins. Modifying protein glycosylation to extend half-life is a clinically proven strategy, but it has not been as extensively used as PEGylation or protein fusion strategies. Many therapeutic proteins that are endogenous replacement proteins (e.g., cytokines, blood factors) or antibodies are naturally glycosylated and produced in glycosylated forms.

Glycosylation can play a significant role in protein bioactivity and pharmacokinetics and can increase solubility [28,29]. Additionally, glycosylation has been found to prevent protein instabilities, including: oxidation, cross-linking, precipitation, pH, chemical or thermal denaturation, aggregation, and proteolytic degradation [185]. Improved stability has been observed for glycoproteins such as G-CSF (Granocyte) [186] and INF-γ (Actimmune) [187]. Many excellent reviews describe the scope of protein glycosylation and the analytical challenges involved with characterization [32,188–191].

Clinically, the dominant platform for glycoprotein production is mammalian expression systems, especially Chinese hamster ovary (CHO) cell lines [32,192,193]. Other methods, including enzymatic, chemical, and chemoenzymatic *in vitro* glycosylation methods, have also been described [32]. CHO expression systems have the ability to produce proteins with N-glycans similar to human proteins; however, effort is required to minimize development timelines from gene to production cell line. Often, control of glycosylation structure is a key challenge with multiple glycoforms being produced [194]. This technology has been applied, for example, to the production of darbepoetin-α (Aranesp), a hyperglycosylated analogue of EPO. Aranesp has two additional N-linked carbohydrates, resulting in a threefold increase in serum half-life and increased *in vivo* activity compared with recombinant human EPO [195,196]. Darbepoetin-α is primarily used to treat anemia associated with chronic kidney disease and HIV infection [196,197].

Much preclinical research has been conducted to find other methods to prepare glycosylated proteins. Yeast-based expression systems have also been examine to produce therapeutic proteins, including mAbs [198]. The major advantages are robust expression, scalable fermentation, and the ability to perform N-glycosylation [199]. Pichia pastoris can be engineered to produce glycoproteins with a high degree of homogeneity, and this yeast system has the ability to optimize the glycosylation for specific therapeutic functions [198,200,201]. Glycoproteins produced in yeast can have a high mannose content, which can induce immunogenicity and can result in a shorter serum half-life [202]. Transgenic plants are also being examined as expression systems to make glycoproteins [32,203–205]. Nonhuman glycan structures that lack galactose and terminal sialic acid that contain xylose and α1,3-fucose can be present [206,207]. Synthetic strategies have also been explored [208,209]. This approach has been applied to make glycosylated EPO. A cysteine tag was used in a solid-phase ligation strategy to introduce an N-glycosylation site followed by chemoselective reaction with glycosyl iodoacetamide [210] or bromoactetamide [211].

### 9.2.3 Fusion Proteins

Another approach to increase the plasma half-life of therapeutic proteins is by recombinantly linking or fusing the protein of interest to another protein that displays extended circulation half-life. Fusion of the protein of interest to the Fc fragment of an IgG is designed to exploit the recycling mechanism with the pH-dependent binding of the neonatal Fc receptor (FcRn) [212]. Human serum albumin also binds to the Fc receptor and has also been used to fuse with a therapeutic protein. Fusion proteins have displayed decreased toxicity [213] and active targeting [214]. Although the vast majority of fusion proteins are produced by recombinant strategies, chemically based conjugation strategies to link two proteins together have also been described [215].

The use of recombinant strategies to produce Fc fusion proteins has been clinically successful. Examples include (Enbrel), Alefacept (Amevive) [216, 217], Abatacept (Orencia) [218], Rilonacept (Arcalyst), Romiplostim (Nplate) [219–221], and Belatacept (Nulojix) [222, 223] (Table 9.2). In addition to half-life

**TABLE 9.2 Examples of fusion proteins [27,212]**

| Product | Company | Fusion Partner 1 | Fusion Partner 2 |
|---|---|---|---|
| *Examples of Clinically Approved Fusion Proteins* | | | |

EpCAM: Epithelial cell adhesion molecule; CTLA4: Cytotoxic T-Lymphocyte Antigen 4; Ig: immunoglobulin; IL: interleukin; IL1Rs: Interleukin-1 receptor; LFA-3: lymphocyte function-associated antigen; TNFR: Tumor necrosis factor receptor; TPO: thrombopoietin; VEGF: vascular endothelial growth factor.

extension, in many cases, fusion of a therapeutic protein with the Fc domain can improve its solubility or stability (e.g., protection from proteolysis) [224]. Interestingly, the serum half-life differs for many of the Fc fusion proteins in the clinic (ranging from 4 to 13 days). For example, the half-life of Enbrel is 4.3 days, but for Alefacept and Abatacept, the half-lives are 11.3 and 13.1 days, respectively [225]. It remains unclear whether the receptor regions of Fc-fusion proteins alter the conformation of the CH2–CH3 domain interface or the regions cause steric hindrance on the binding site of FcRn.

Albumin fusion has also been examined to extend the circulatory half-life of therapeutic proteins. Albumin also bind to FcRn, which is necessary for observed circulation half-life of 19 days for albumin [226]. Although albumin is a complex protein, one appeal for using it as a fusion partner that was often cited is the albumin avoids effector functions that can be associated with some Fc regions. The first reported albumin fusion was with CD4. There was a 140-fold increase in the circulation half-life of $0.25 \pm 0.1$ h for CD4 to $34 \pm 4$ h for the albumin–CD4 fusion in the rabbit. The binding and *in vitro* anti-viral activity of CD4 for the albumin–CD4 fusion was similar to those of soluble CD4 [227]. Further development of albumin fusion technologies has focused on proteins that have been used clinically, for example, cytokines including INF-β [48], INF-α2b (Albuferon) [47,228], growth hormone (Albutropin) [229], G-CSF (Albugranin) [46], EPO [230] and interleukin-2 (IL-2) (Albuleukin) [231]. Additional examples include hirudin [232], factor VIIa [233], and thioredoxin-1 (Trx) [234] and bispecific antibodies [235]. Peptides include glucagon-like peptide-1 (GLP-1) (Albugon) [236], insulin (Albulin) [237] and recombinant B-type natriuretic peptide (AlbuBNP) [238] to treat congestive heart failure. Several of these albumin fusion proteins have been evaluated in preclinical studies. A few albumin fusions have been evaluated in clinical trials, including Albutropin, AlbuBNP, and albumin IL-2. Albuferon (INF–albumin fusion) appears to have progressed the furthest in clinical development; unfortunately, phase III trials were stopped.

Recombinant fusions of therapeutic proteins to transferrin (Tf) have also been evaluated preclinically. Tf is a blood plasma glycoprotein that reversibly binds ferric ions at physiological pH and is important for the control of the amount of iron in the blood. When Tf is bound to iron, it can bind to a Tf receptor (Tfr) on the cell surface and is transported into the cell by receptor-mediated endocytosis. The acidic pH in the endosomal compartment of the cell causes Tf to release its iron ions, and then Tf together with Tfr is recycled to the cell surface [239]. Fusion with Tf, which is resistant to enzymatic digestion, allows it to be considered a stable protein partner for use in fusions with the potential for extended half-life being possible. Tfr is expressed in high numbers on epithelial cells. Therefore, Tf fusions have been considered for oral drug delivery. Recently, human growth hormone–Tf fusion was evaluated in preclinical studies [240]. Tf fusion technology has also been applied to GLP-1 and exendin-4 (EX-4) in efforts to improve their pharmacology [241].

Fundamentally, there are several disadvantages with attempting to recombinantly fuse proteins together. It is often difficult to isolate a fusion protein pure in sufficient

amounts during early development and at scale for production [242,243] because there is often an increased propensity for aggregation and enhanced degradation [244,245]. Therapeutic fusion proteins have not evolved to be together [246–248] so it can be difficult to ensure that each of the fused proteins is correctly folded and that there is an optimal sequence of amino acids that link the two proteins together. The flexibility, composition, and appropriate length of the polypeptide linker between the proteins to be fused are important factors [249] that must be optimized [250–255]. It also is unfavorable to have a linker sequence with a high propensity for forming α-helical or β-strand structures because this limits the flexibility of the fused proteins and affects their functional activities. Moreover, the linker potentially can be a source of immunogenicity [256]. Although computational methods can be used to design the linker sequence [257], linker selection still remains a challenge in the construction of functional fusion proteins.

## 9.3 STRUCTURE-BASED ENGINEERING TO MODIFY PROTEIN AND PEPTIDE THERAPEUTICS

The continuous improvement in DNA technologies has resulted in strategies to modify protein structure. It is not only possible to produce recombinant protein-based therapeutics but also to engineer favorable properties that can improve biological and physiochemical characteristics of a protein of interest [258].

### 9.3.1 Sequence-Based Modifications

Endogenous human proteins are expressed *in vivo*. Many are often expressed in low concentration, sometimes as pro-variants, and often have an immediate effect on their target. These proteins have also evolved to function within the physicochemical environment of the body. In contrast, therapeutic proteins are exposed to a variety of chemical and physical stresses during production and downstream purification. They are also stressed during formulation processes, and while stored and used as final dosage forms.

Recombinant variants of endogenous and novel proteins that are being developed as therapeutics can often be engineered to display improved solubility and stability. Maintaining protein stability throughout its lifetime from production to clinical use poses many challenges. Site-directed mutagenesis to modify protein structure can be achieved with high fidelity [259] to make the protein more robust in regards to proteolysis, oxidative stress, or temperature and pH changes [5]. Such efforts can help to decrease the propensity for unfolding, aggregation, and degradation processes that can compromise protein function. Other strategies include diversity methods, such as phage display, or semirational protein design methods [5] (Table 9.3).

For example, proteins can potentially be stabilized by introduction of disulfide bond [260], removal of free cysteine [261], or modulation of the internal hydrophobicity of the protein [262]. Replacement of free cysteines can prevent the formation

**TABLE 9.3 Recombinant Strategies for Protein Modification [258]**

| Issue Addressed | | Engineering Strategy | Example |
|---|---|---|---|
| Lack of posttranslational modifications in *Escherichia coli* | Glycosylation | Expression without the glycosylation (only if the biological activity is not impaired) | IL-2 [355] |
| | | Mutation of residues on the surface to create more soluble protein | EPO [356] |
| | | Mutation of glycosylation sites to cysteines to allow subsequent glycosylation *in vitro* | EPO [210] |
| | Proteolytic maturation | Expression in two separate strains or cleavage of the precursor *in vitro* | Insulin [357] |
| | Disulfide bridge formation | Expression in the periplasmic space | hGH, proinsulin [358] |
| Protein stability | | Decreasing number of free cysteine residues by mutation to alanine | IL-2 [359,360], IFN-β1 [261] |
| | | Deletion of the hydrophobic region | KGF [361] |
| Modulation of protein activity | | Design of the rapid-acting or long-acting protein version | Insulin [362] |
| | | Enhanced activity by improved affinity to the target molecule | DNaseI [363] |
| | | Design of protein consisting of a consensus sequence | IFN-α-con [364] |

hGH: human growth hormone; IFN: interferon; IL: interleukin; KGF: keratinocyte growth factor.

of undesired intermolecular or intramolecular disulfide bonds. This approach has been successfully demonstrated on several therapeutically relevant proteins with important clinical applications, such as INF-β1b [263], G-CSF [264], and human fibroblast growth factor (FGF) [5].

Another methodology is to increase the stabilizing factors that influence protein folding. As a good first approximation, protein folding is driven by hydrophobic properties of nonpolar amino residues. Strengthening of internal hydrophobicity by amino acid substitution may increase protein stability [265]. This approach is often aided by using computational design methods, which are used to optimize packing and hydrophobic interactions within the folded protein [266,267].

Protein structure can be also improved by optimizing the propensity for localized secondary structure, hydrogen bonds, and electrostatic interactions [268]. This approach has been successfully applied to clinically relevant proteins, including G-CSF and human growth hormone [269]. The optimized variant of site-specifically mutated G-CSF displays enhanced thermal stability and prolonged shelf life while maintaining the desired biological activity [5].

An additional aspect of protein stabilization is to reduce the susceptibility of a protein to proteolytic degradation. If the sequence within a protein that is prone to proteolysis can be determined, it can be genetically modified so it is no longer recognized by the putative protease. Frequently, protease cleavage sites are located in a flexible loop of the protein structure; therefore, one approach of introducing site-specific modification, which reduces the flexibility of the loop, may lead to the reduction of protein's propensity for proteolytic degradation.

As expected, care must be taken to maintain protein structure and biological activity [5], but this approach has been used for factor VIII-a. For blood clotting factors, specific proteolytic susceptibility is important for activation and inactivation. The coagulation factor VIII-a with increased resistance to proteolytic inactivation was developed by genetic mutation of two arginines, which are required for cleavage by thrombin, factor Xa, and activated protein C [270].

Maintaining protein solubility during production, formulation, and administration processes is another important issue associated with the development of effective therapeutics. Proteins are usually expressed and then formulated at relatively high concentrations, which can result in aggregate formation. Aggregation can cause a decrease in protein activity, reduced bioavailability, and potentially increased immunogenicity. Several strategies to minimize aggregation by protein engineering have been developed and demonstrated on clinically important proteins.

For example, replacement of an unpaired cysteine residue prevents formation of undesired intermolecular disulfide bonds during processing, which can lead to aggregation. Substitution of solvent exposed nonpolar residues with polar residues may lead to improvement in protein's solubility. An example is the A1 domain of cholera toxin, in which a variant with significantly improved solubility and retained biological activity was obtained [271]. Another approach is to alter the net charge of protein to change the isoelectric point (pI), which also can lead to improvement of protein solubility. An example of this approach is with a single-chain antibody targeting renal cell carcinoma. The protein sequence was altered by adding five glutamic acid residues to the C-terminus, leading to lowering the pI from 7.5 to 6.1 and therefore increasing its solubility [272]. Many of these modification strategies have been used with the clinically used insulin analogues that have been developed.

Identification and reduction of potential immunogenicity are key safety concerns [19,80]. The clinical use of protein-based medicines is complex. Many patients treated with proteins may develop immune response [23]. There are consequences from the processes used in the manufacture of proteins as well as the inherent complexity of protein structure and how they are administered. In addition to immunogenic effects, unwanted side effects such as an increased susceptibility to infections or malignancies may develop during treatment or after treatment has

stopped [9]. Postapproval safety-related regulatory actions have been issued for approximately 23% of protein-based medicines in the United States and European Union [9]. Immune responses to a protein therapeutic may also alter pharmacokinetics, reduce efficacy, cross-react with an endogenous protein, and cause an adverse reaction [19]. Immunogenicity may also lead to life-threatening situations if the produced antibodies not only neutralize the administrated therapeutic but also neutralize the endogenous protein [79].

Protein immunogenicity [6,81] may be caused by numerous factors, which may be categorized into three main groups: structure-related characteristics of the protein, product related-factors [22,83], and patient-related factors [273]. The presence of heterogeneous mixtures may contribute to long-term safety related issues of protein-based medicines [83]. A significant structural factor is the degree of nonhuman sequence within the protein. Additionally, immunogenicity may be caused by noncovalent-derived structural changes of the protein, such as protein mis- or unfolding and protein aggregation, which will result in presentation of new amino acid arrangements on the surface of the protein.

Although this still remains a complex task, recent advances in mass spectrometry and computational epitope mapping can be used in efforts to reduce immunogenicity [274,275]. This approach is very useful for nonhuman proteins. A clinical example is staphylokinase, which is a bacterially derived protein that activates human plasminogen for thrombolysis. Staphylokinase (and streptokinase) are generally used in acute situations unlike many protein therapeutics that are dosed over a period of time. However, avoidance of immunogenic reactions is still important for patient safety. A reduction in its immunogenicity was obtained by site-specific mutagenesis in which 13 amino acids were substituted to alanine [276].

### 9.3.2 Humanization of Nonhuman Proteins

Investigation of the potential for protein immunogenicity and how it can be reduced is a necessary aspect in the development process [19,23,81,277]. Protein engineering provides valuable tools in efforts to manage immunogenicity, such as humanization of nonhuman proteins (e.g., insulin analogues and mAbs) or structure-based modifications to remove immunogenic epitopes [20,22,278,279]. In this second approach, the primary sequence of a protein, which is recognized by the immune system, can in principle be reengineered so it is no longer recognized as foreign. This process can be facilitated using epitope mapping, which allows T- and B-cell epitopes to be identified and subsequently modified [275,280–282]. For many therapeutics, especially mAbs, a decrease in therapeutic immunogenicity is obtained by changing the protein sequence from murine to fully human [283].

The widespread use of therapeutically relevant mAbs has led to development of technologies to humanize their sequence. The human anti-mouse antibody (HAMA) response is common for murine antibodies. The HAMA response neutralizes the administered antibody to reduce efficacy and can also cause anaphylactic shock [284]. One study found that out of the 40 antibodies that have been in the clinic, 84%

had marked HAMA reactions, 7% had tolerable HAMA, and only 9% were found to exhibit negligible HAMA reactions [285].

The strategy of "humanization" [286] was accomplished first with the constant regions of antibodies to make chimeric and increasingly more humanized versions. Humanization of antibody variable regions has been more recent. The variable regions comprise the complementarity-determining regions (CDRs), which constitute the antigen-binding site and framework regions (FRs), which form the scaffold around the binding site. CDR grafting has been successful to reduce immunogenicity, although there can be a reduction in the binding affinity of the antibody [287]. As the amino acids of the scaffold interact with those of the CDR regions, it is also necessary to back mutate some of the key residues found here that are important for maintain binding site integrity with the aim of retaining as much binding affinity as is possible. This approach has proved so effective that humanized antibodies now represent half of the current FDA-approved mAbs on the market [286].

One such antibody, Zenapax (daclizumab), was the first humanized antibody approved by the FDA in 1997 for human therapeutic for use in the United States and is used to prevent renal allograft rejection. It is a humanized IgG1 form of the mouse mAb anti-Tac, an anti-human IL-2 receptor chain (CD25) antibody that blocks the interaction of IL-2 with the IL-2 receptor and thus prevents the activation of T cells [287]. Humanization of this antibody led to 14% low titer of anti-idiotype A antibodies and 34% lower in pediatric patients compared with the nonhumanized antibody [285].

Another more recently approved humanized antibody that benefited from humanization was the murine anti-CD3 antibody (muromonab), which was found to elicit neutralizing antibodies after a single dose in all patients tested; a humanized version was immunogenic in only 25% of patients after multiple injections [285]. Novel antibodies are being developed as their humanized version. Although immunogenicity may be reduced compared with murine and chimeric versions, many mAbs still display considerable toxicities that have to be monitored, especially in oncology and inflammation.

## 9.4 PROTEIN MODIFICATION TO ADD A THERAPEUTIC EFFECT

The modification approaches previously described in this chapter are aimed at improving the properties of a therapeutic protein or peptide. In contrast to this, conjugation of drugs to proteins or peptides mainly aims to improve the therapeutic properties of the small molecule drug. The main clinical area is oncology as many of the small molecule drugs are cytotoxic with the need to increase their therapeutic window to improve efficacy.

The protein or peptide component of such a conjugate as well as the linker can be regarded as a carrier that helps to improve the solubility, stability, pharmacokinetics, bioavailability, biodistribution or localization, selectivity, toxicity profile, targeting potential, and, ultimately, therapeutic index of the drug component. However, the efficacy of a therapeutically active protein or peptide can also be enhanced by conjugation to a pharmacologically active drug (payload) that would give it new therapeutic functions.

Currently, at least five protein-drug conjugates (PDCs) are approved for treatment, and many more are at different stages of development. Due to the clinical success of protein–drug conjugates, the interest in this field has increased at an accelerating rate over the past decade. This is reflected by the growing number of research publications, candidate compounds in development, and conferences and commercial deals, as well as a large range of excellent reviews for the main types of conjugates, such as albumin–drug conjugates, antibody-drug conjugates (ADCs), and radioimmunoconjugates.

The most important motivation for conjugating drugs to proteins and peptides is the potential to widen the therapeutic window of the drug by targeting its delivery to specific cell types, tissues, or organs. The concept of targeted chemotherapy is more than a century old and was first described by Paul Ehrlich, who proposed the idea of creating "magic bullets" to treat all human diseases.

Despite the numerous and significant advances for therapies in oncology, most current therapeutic agents have relatively low selectivity, a low therapeutic index, and a narrow therapeutic window. Most anticancer drugs have to be dosed at near their maximum tolerated dose (MTD) to achieve a therapeutic effect. In addition to the development of drug resistance, many severe side effects are frequently associated with current chemotherapies. These include nephrotoxicity, hepatotoxicity, bone marrow toxicity, neurotoxicity, cardiovascular toxicity, mucositis, and gastrointestinal toxicity. These unwanted side effects can lead to serious complications that are difficult and expensive to treat, are dose-limiting, and can prevent effective treatment and can force the discontinuation of lifesaving treatment.

As a result, cures are achieved only in a small set of cancers and patients. However, there have been some clinical successes for several targeted therapy approaches in the past 15 years that have brought a new wave of optimism. A few notable examples are the development of highly efficacious mAbs, tumor-specific kinase inhibitors, and, maybe the most promising of all, ADCs that combine the specificity of an antibody with the cytotoxicity of a highly potent chemotherapy drug.

### 9.4.1 Protein– and Peptide–Drug Conjugates as Strategies for Targeted Drug Delivery

These conjugates comprise a protein, a linker, and an active agent that is covalently conjugated to the protein or peptide via the linker. The principle underlying protein– and peptide–drug conjugate (PDC)-based targeted drug delivery strategies is that the protein component has affinity for the target site, where the drug can be released (often intracellularly). Selective drug release is a key requirement for most active agents because their pharmacological activity relies on binding to cellular targets. However, radioisotopes have a different mode of action and do not have to be released at the target site [288–290].

PDCs have a multistep mechanism of action, with the different steps having different and even contradictory requirements. Ideally, the PDC should be stable during storage, nontoxic, stable, and inactive in circulation during its journey to the target site, where drug should then be released. The whole PDC can be regarded as a drug precursor, which should be systemically nontoxic. The requirement for this

conditional stability is key to the specific delivery of a drug to the intended target site and makes the development of PDC therapeutics challenging.

The accumulation of the protein at the target exploits the morphological and physiological differences between the disease target site and healthy cells, tissues, and organs. Passive targeting strategies have been used to exploit the passive accumulation of large macromolecules in some malignant and inflamed tissue caused by a leaky vascular system combined with a defective drainage system, which is known as enhanced permeability and retention (EPR) [291,292–295].

Strategies that aim at increasing the molecular mass and hydrodynamic volume of a drug (e.g., conjugates to large proteins or polymers, nanoparticles, micelles) mainly rely on EPR. However, EPR is not specific for the drug conjugate because it occurs for all other macromolecules in circulation. Although enhanced accumulation in some tumors has been demonstrated for large drug conjugates compared with the free drug, in some cases (e.g., nanoparticles that are devoid of any active targeting mechanisms) 95% of the administered dose accumulated in other nontarget organs such as the liver, spleen, and lungs [295]. Because the majority of the administered dose accumulates in nontarget sites, Bae and Park [295] have suggested that the term "passive targeting" is a misnomer, and it should be replaced with "blood circulation and extravasation" to reflect its nonselective nature.

Active targeting exploits the affinity of the carrier protein for specific antigens or receptors that are either uniquely expressed or overexpressed on the target site [296,297]. The targeting or guiding molecule can be a peptide, mAb, antibody fragment, growth factor, hormone, or any other protein that binds specifically to the target antigen or receptor. Of all of the protein–drug conjugates, ADCs are attracting by far the most attention.

### 9.4.2 Antibody–Drug Conjugates

Monoclonal antibodies are established as very useful therapeutic agents in oncology. However, only a few antibodies that target hematological malignancies, such as rituximab (anti-CD20) and alemtuzumab (anti-CD52), are effective as single-agent therapies to date. Antibodies targeting solid tumors, such as trastuzumab and pertuzumab (anti-HER2), cetuximab and panitumumab (anti-EGFR), or bevacizumab (anti-VEGF), are ineffective as single-agent therapies and have to be used in combination with cytotoxic drugs. There are many different mechanisms through which antibodies exert their anticancer activity, such as antibody-dependent cytotoxicity (ADCC), complement-dependent cytolysis (CDC), antibody-dependent phagocytosis (ADP), interference with cellular signaling, depletion of circulating tumor cells, or induction of apoptosis. Despite this, they are unable to sustain a lasting effect and thus have a very limited curative potential.

At the same time, although many small molecule drugs are very potent against cancer cells, their effective clinical use is limited by low selectivity and high toxicity to nontarget tissues. ADCs constitute a very promising approach to combine the best features of antibodies, such as high target selectivity, low systemic toxicity, and long circulating half-life with the high potency of cytotoxic drugs or radionuclides.

ADC technology is being investigated by a wide range of pharma and biotech companies, reflecting their confidence in the potential for clinical and commercial success of this approach. As of April 2013, Thomson Reuters' Integrity database listed 170 ADCs, with 9 products launched and 43 products at different stages of clinical development (including drug and radionuclide conjugates for both therapeutic and diagnostic use).

***9.4.2.1 Brief Overview of ADC History*** Only three therapeutic ADCs have ever been approved for treatment. The first one, gemtuzumab ozogamicin (Mylotarg), was conditionally approved in 2000. In postapproval phase III trials, gemtuzumab ozogamicin failed to demonstrate a survival benefit over conventional therapy and was associated with a higher rate of fatal toxicity than in the control arm [298]. Despite controversy in the medical literature about this study, Pfizer voluntarily withdrew it from the market in 2010. Currently, there are several ongoing phase II and III trials examining gemtuzumab ozogamicin in a range of indications and patient subpopulations. Recent results from phase III trials in patients with acute myeloid leukemia (AML) showed a significant clinical benefit for combining standard induction therapy with lower dose or fractioned lower doses of gemtuzumab ozogamicin [298].

The second ADC, brentuximab vedotin (SGN-35, Adcetris), was granted accelerated approval by the FDA in August 2011 based on results from single-arm phase II trials in Hodgkin's lymphoma and anaplastic large cell lymphoma, which demonstrated an acceptable toxicity profile and remarkable objective response rates of 73% and 86%, respectively [299]. The third ADC, trastuzumab emtansine (T-DM1, Kadcyla), demonstrated significantly prolonged progression-free and overall survival compared with standard treatment in patients with HER2-positive advanced breast cancer who were previously treated with trastuzumab and a taxane (the EMILIA trial) [300]. It was granted approval by the FDA in February 2013.

The recent successes in the ADC field follow on from over three decades of sustained research efforts and are a tribute to the lessons learnt from the many previous failures. Historically, the different phases of ADC development follow very closely the development of cytotoxic drugs.

***9.4.2.2 First-Generation ADCs*** During the 1980s, chemotherapy drugs such as doxorubicin, methotrexate, cisplatin, or vinca alkaloids were used. These were well-characterized and already approved drugs to treat cancer [301–304]. When examined *in vivo* in xenograft tumor models in mice, several ADCs demonstrated significant antitumor activity because of enhanced tumor accumulation (10–30% ID/g of tumor) compared with the free drug.

However, clinical evaluation of three such conjugates failed to demonstrate a therapeutic benefit or clinical response. Moreover, the ADC that progressed to phase II trials in gastric adenocarcinoma and metastatic breast cancer, BR96–doxorubicin (SGN-15), proved less effective than unconjugated doxorubicin [301,303]. The explanation is that the ADC failed to deliver sufficient (therapeutic) concentrations

of drug to the tumor cells. Several contributing factors have been identified, such as insufficient drug potency, low density of antigen expression, poor internalization and drug release, low tumor localization, linker instability leading to premature release of drug in circulation, and the occurrence of anti-ADC neutralizing antibodies.

The discord between the observed *in vivo* animal studies and clinical antitumor activity can also be explained by the very different tumor uptake of specific antibodies in patients (0.003–0.08% ID/g of tumor) and in mouse xenograft models (10–30% ID/g) [299]. An average human is 3000-fold greater in body weight than a mouse; therefore, each gram of tumor is diluted into 3000-fold more body weight and that 10 to 30% ID/g in mouse is approximately equivalent to 0.01 to 0.003% ID/g of tumor in human patients [303]. Also, in some cases, the human tumor-associated antigens targeted had no or insufficient homology with the rodent antigens, leading to significant underestimation of on-target toxicity and an overestimation of tolerability and therapeutic index. Consequently, since the 1990s, as well as developing more potent cytotoxic drugs, which are active in the concentration range of antibody accumulation in tumors ($IC_{50}$ values of 0.01 to 0.1 nM) [301], and novel linkers that are stable in circulation and allow rapid release of the drug in its most active form inside the tumor cells, the focus has also been on developing more predictive *in vivo* models.

***9.4.2.3 Second-Generation ADCs*** Second-generation ADCs use cytotoxic drugs that are 100- to 1000-fold more potent *in vitro* than the drugs used by the first-generation ADCs. Clinical-stage ADCs use one of the following cytotoxic drugs: Wyeth/Pfizer's calicheamicin ($IC_{50}$ $10^{-10}$–$10^{-9}$ M), ImmunoGen's maytansinoids DM1 ($IC_{50}$ $10^{-11}$–$10^{-9}$ M) and DM4 ($IC_{50}$ $10^{-12}$–$10^{-11}$ M), Seattle Genetics' auristatin E ($IC_{50}$ $10^{-11}$–$10^{-9}$ M) and auristatin F ($IC_{50}$ $10^{-8}$–$10^{-7}$ M), or the Medarex/BMS's MGBA (minor groove binding agent) duocarmycin analog (CC-1065) ($IC_{50} < 10^{-9}$ M).

ADCs using a double prodrug approach are sometimes referred to as *third-generation ADCs*. One such example is the Medarex UltiMab approach involving conjugation of MGBA to antibodies through a cleavable peptidic linker. The cleaved MGBA–linker adduct has reduced potency and requires a further activation step by intracellular carboxyesterases before releasing the active drug [305]. One such ADC targeting CD70 (MDX-1203) is currently being evaluated in a proof-of-concept phase I clinical trial.

***9.4.2.4 Key Features of ADCs*** ADCs are a clinically validated strategy for generating therapeutics with improved efficacy and tolerability. However, the ADC strategy has yet not met the promise of the "magic bullet." Only a small proportion of the administered drug ever reaches the tumor and a similar profile of dose-limiting nontarget toxicities was observed for all ADCs for which clinical results have been reported [306–309]. The past couple of decades have seen major advances in understanding the *in vivo* behavior of ADCs. However, there are very few general rules and there is little about ADCs that can be rationally predicted and designed. The ADC field remains largely experimental with the design and optimization of novel ADCs still dominated by an empirical trial and error approach.

Ongoing efforts are focused around key features of ADCs, such as the target antigen and antibody, payload, conjugation site, stability and stoichiometry, type of linker, and mechanism of payload release. Currently, there are over 30 ADCs under clinical evaluation; clinical data from the many ongoing trials will become available over the next few years and will guide further optimization of ADCs.

***9.4.2.5 Selection of Suitable Target Antigen and Antibody*** Antigen selection is one of the most important factors determining the selectivity of payload delivery to the target cancer cells. The ideal target antigen would be uniquely expressed on the cancer cell; however, such antigens have not yet been identified. Most antigens targeted by ADCs are tumor-associated rather than tumor-specific and are expressed on the cancer cells only at higher densities than on normal cells [297]. In most cases, binding to the antigen triggers the internalization of the ADC into the target cell and subsequent trafficking to specific subcellular compartments where the drug component is released or converted to its fully active form. In general, the antigens targeted by ADCs are internalized by receptor-mediated endocytosis and delivered into the endocytic pathway, often ending up in the lysosomal compartment [301,310,311]. However, the rate and extent of internalization and subcellular trafficking depend on the biology of the cell surface antigen or receptor. Some receptors internalize continuously regardless of whether a ligand is bound or not, but other receptors, such as the epidermal growth factor receptor, internalize at an accelerated rate when the natural ligand or ligand-mimetic protein is bound [301].

A small number of antigens and receptors, such as CD20 or CD21, are very poorly internalized or reside permanently on the cell surface [312]. Even when targeting a well-characterized antigen, the behavior of an ADC cannot be predicted. For instance, conjugation of the cytotoxic drugs doxorubicin or auristatin to rituximab, a noninternalizing anti-CD20 antibody, yielded ADCs that were internalized and delivered to the lysosome with great efficiency [313]. However, the same was not true when rituximab was conjugated to calicheamicin, a different cytotoxic drug [314].

For other antigens, such as CD30, both the naked antibody and the auristatin conjugates have been shown to internalize with similar rates [315]. Another interesting example is given by L49, a normally noninternalizing antibody targeting the p97 (melanotransferrin) antigen. In contrast with the naked antibody, the auristatin conjugates exhibited very efficient internalization and trafficking to the lysosome in antigen-expressing sensitive cell lines. However, in a subgroup of antigen-positive but nonresponsive cell lines, the internalized ADC was trafficked away from the lysosome through caveolae-mediated transport to locations lacking proteolytic activity, where drug release and function were prevented [311,316].

These examples suggest that internalization and subcellular trafficking depend not only on the nature of the antigen but also on the nature of the drug molecule, conjugation technology used, and cell phenotype, among many other potential factors. The antigen density on the target cells, as well as rate of internalization and subcellular trafficking, will determine the concentrations of payload that can be achieved in the target cell, and hence will drive efficacy. However, the relative level

of expression on normal cells compared with target cells is also extremely important as this will drive the on-target toxicity and tolerability profiles.

It is not surprising that the two recently approved ADCs that have shown favorable safety profiles and remarkable clinical efficacy, brentuximab vedotin and trastuzumab emtansine, target CD30 and HER2, respectively, which are antigens that are highly overexpressed on cancer cells compared with normal cells and that are internalized very efficiently [298]. For a long period, it was thought that internalization or trafficking to the lysosome is essential for optimal ADC activity [311]. However, there have been reports of good *in vivo* and clinical efficacy with ADCs targeting antigens expressed at relatively low levels on the cancer cells [298] or ADCs that are poorly internalized and thus release the drug extracellularly [314,317]. Alternative strategies that have recently given encouraging results target noninternalizing antigens overexpressed on the endothelial cells or subendothelial extracellular matrix of tumor vasculature [302,318,319].

***9.4.2.6 Selection of Payload Release Mechanism: Linker Design*** Selective release of the drug at the target site is usually achieved by incorporating special features into the linker between the drug and the antibody [305,320–323]. Three main types of linkers have been described: (1) chemically cleavable linkers, (2) enzymatically cleavable linkers, and (3) noncleavable linkers. Linker design strategies are based on the physiological differences between the extra- and intracellular compartments for internalizing ADCs or the differences between the extracellular space of target and nontarget tissues for noninternalizing ADCs.

Early developments focused on exploiting the pH difference between these compartments and used acid-labile hydrazone linkers, which have been described in many preclinical studies. A hydrazone linking moiety is more stable in the neutral environment of the blood (pH 7.3–7.5) than in the acidic intracellular environment of the endosome (pH 5.0–6.5), lysosome (pH 4.5–5.0), or tumor pericellular space, where such linkers can be readily hydrolyzed to release the active drug [305,322].

The first ADC to be granted FDA approval, gemtuzumab ozogamicin (Mylotarg), involved random conjugation of calicheamicin through an acid-labile hydrazone linker to the solvent-exposed lysine residues of an anti-CD33 mAb. The disappointing performance of Mylotarg was associated with insufficient plasma stability of the acid-labile linker leading to premature release of toxic amounts of calicheamicin in circulation [321,324]. Acid-labile linkers are generally considered relics of the early days of ADC development, which are unable to confer sufficient plasma stability to an ADC. However, inotuzumab ozogamicin (CMC-544), a calicheamicin conjugate to an anti-CD22 antibody using identical linkage chemistry to Mylotarg, has demonstrated very good serum and plasma stability and promising clinical efficacy with an objective response rate of 68% for follicular non-Hodgkin's lymphoma and 15% for diffuse large B-cell lymphoma. It is currently being evaluated in phase III trials [305,325,326]. Other examples of linkers that undergo proton-catalyzed hydrolysis at low pH incorporate biodegradable polymers, such as hydrophilic polyols [327,328].

Another type of chemically cleavable linkers are those containing a disulfide, which is cleaved upon exposure to a free thiol [305]. Cleavage selectivity is based on

the presence of glutathione (a thiol-containing tripeptide) inside the cell at concentrations that are three orders of magnitude higher than in blood, that is, millimolar versus micromolar. Moreover, the hypoxic state of many cancer cells can lead to further accumulation of glutathione in the intracellular or pericellular space. However, it is well known that thiol-selective maleimide moieties can undergo exchange reactions *in vivo* with free thiols from other proteins such as albumin [145], so a disulfide-linked ADC would be expected to be labile during circulation.

Recently, Bernardes et al. [319] have reported a novel linkerless approach that involves direct conjugation through disulfide bonds of a thiol-containing cytotoxic drug to the engineered cysteine residues of an antibody. Selective cleavage of the disulfide bond in the reducing tumor microenvironment generated only two species, the antibody and the cytotoxic drug, making this ADC traceless. Although the strong antitumor activity seen for this noninternalizing vascular-targeting ADC in a murine tumor model is very encouraging, it remains to be established whether such a conjugate would have sufficient plasma stability for human treatment.

Another approach is to use enzymatically cleavable linkers containing peptide sequences, for example, valine–citrulline, phenylalanine–lysine, or the more hydrophilic valine–lysine sequence, that are cleaved by lysosomal proteases such as cathepsin or plasmin [305,329]. Such peptide linkers can exhibit very good serum stability often 100-fold greater than their chemically cleavable counterparts. Alternative enzyme-cleavable linkers contain β-glucuronide, a carbohydrate moiety, as the cleavage site [330–333]. Such linkers are more hydrophilic than peptidic linkers and are readily cleaved by β-glucuronidase, an enzyme present in the lysosomal compartment and in the interstitial space of many tumors. Enzyme-cleavable linkers often contain self-immolating spacers between the drug and the cleavage site. Such spacers not only distance the drug from the cleavage site to avoid steric hindrance allowing efficient enzymatic cleavage, but also, upon enzymatic cleavage, initiate a cascade of reactions that result in the release of the drug in its most active form, free from any linker adducts [305].

Another option is to use stable, noncleavable linkers to link the drug to the protein- or peptide-guiding molecule. The use of such linkers requires ADC internalization and delivery to the highly catabolic lysosomal compartment, where the protein or peptide backbone is completely degraded, releasing the drug and its linker. The condition for the success of this approach is that the drug remains active when conjugated to the linker moiety [334,335].

Noncleavable linkers are by far the most stable in circulation but are often hydrophobic. This can lead to issues with aggregation, can limit the drug loading, and can have a negative impact on the functionality of the targeting molecule, the pharmacokinetic profile of the ADC, and the pharmacology of the released drug–linker compound [305]. To address these limitations, novel hydrophilic linkers containing either a negatively charged α-sulfonic acid group or a polar short PEG chain have been synthesized [336,337]. Additionally, phosphonic acid and tetraalkyl ammonium derivatives have also been used to improve the solubility of the linker and the resulting ADC [338].

***9.4.2.7 Payload Selection: Matching the Payload and Linker*** Depending on their mechanism of action, the payloads adopted in ADCs at clinical stages of development can be grouped into tubulin-targeting payloads (Seattle Genetics' auristatins or ImmunoGen's maytansinoid drugs) and DNA-intercalating payloads (Pfizer's calicheamicin and the CC-1065 duocarmycin analog from Medarex). There is also one ADC in phase I that uses SN-38, a topoisomerase 1 inhibitor (Labetuzumab-SN-38, Immunomedics), and one that uses doxorubicin, a first-generation tubulin inhibitor (Milatuzumab-doxorubicin, Immunomedics) [298,339,340].

ImmunoGen and Seattle Genetics have licensed their drug-linker technologies to multiple biopharmaceutical companies, so most ADCs under clinical development use one of the two technologies.

Seattle Genetics' auristatin cytotoxic drugs are conjugated to the reduced cysteine residues of the interchain disulfide bonds of IgGs through either enzyme cleavable maleimidocaproyl-valine-citruline-*p*-aminobenzyl linkers (MC-vc-PAB-MMAE/F) or noncleavable maleimidocaproyl linkers (MC-MMAF). Brentuximab vedotin (Adcetris) consists of an anti-CD30 mAb with MMAE conjugated to an average of four cysteine residues via an enzyme cleavable valine–citrulline linker. Upon internalization, the linker is cleaved by lysosomal proteases, and the self-eliminating PAB spacer releases unmodified free MMAE intracellularly [304,321].

All clinical-stage ADCs with MMAE use a -vc- cleavable linker because noncleavable linker MMAE constructs display reduced potency. On the other hand, MMAF is more tolerant to linker modifications and has been used with both cleavable -vc- linkers (e.g., SGN-75, AGS-16M8F) and noncleavable -mc- linkers (e.g., SGN-19A). The higher potency of free MMAE compared with free MMAF seen *in vitro* is mainly attributable to the higher cell penetrability of MMAE. However, when delivered inside the cell by an ADC, the two compounds display similar potency [334].

ImmunoGen's Tumor-Activated Prodrug (TAP) technology and antibody–maytansinoid conjugates (AMCs) consist of antibodies linked at lysine residues via either a cleavable disulfide linker (SPP-DM1 or the disulfide hindered SPDB-DM4) or a noncleavable thioether linker (MCC-DM1) to three to four cytotoxic drug molecules [341]. For some AMCs, such as trastuzumab emtansine (T-DM1), the disulfide cleavable and thioether noncleavable variants showed very similar antitumor activities *in vivo* in xenograft models, but the noncleavable-linked conjugate displayed better serum stability, so it was chosen for clinical development [342]. Cantuzumab emtansine (huC242-SPP-DM1) was evaluated in phase I trials but was subsequently discontinued because of linker instability. The half-life of the conjugate was significantly shorter than the half-life of the antibody component ($t_{1/2}$ conjugate = 41 h vs. $t_{1/2}$ antibody = 230 h).

Kellogg et al. [341] generated a panel of conjugates incorporating disulfide cleavable linkers with different degrees of steric hindrance around the disulfide bond, as well as a control conjugate with a noncleavable linker. Increasing the degree of steric hindrance around the disulfide bond resulted in increased serum stability of the conjugates, but all conjugates displayed similar *in vitro* activities. However, when evaluated *in vivo* in xenograft models, the conjugates with highly hindered disulfide linkers, as well as the conjugates with noncleavable linkers, displayed only marginal

activity, but the huC242-SPDB-DM4 conjugate with a linker with an intermediate level of disulfide hindrance displayed the best efficacy. This can be partially explained by the observation that the DM4 maytansinoid metabolite released from the SPDB-DM4 linker was more potent at inhibiting tumor growth than DM1, suggesting that the *in vivo* antitumor activity of an AMC depends on other factors in addition to conjugate potency and half-life [341]. huC242-SPDB-DM4 (IMGN242) has been evaluated clinically (I/II) but has been discontinued because of the requirement for personalized dosing and slow patient recruitment. However, several other ADCs conjugated with SPP-DM1, such as lorvotuzumab mertansine (IMNG901, phase I/II), or with SPDB-DM4, such as BT-062 (phase I/II), IMNG-388 (phase I), and SAR3419 (phase I), are currently under clinical evaluation.

Currently, there are approximately 16 compounds in clinical development that use Seattle Genetics' technology, including one with FDA approval, and seven compounds use ImmunoGen's TAP technology, including one with recent FDA approval. Only one ADC using Seattle Genetics' technology has been discontinued from clinical development for undisclosed reasons, and six of ImmunoGen's TAP compounds have been discontinued for reasons including narrow therapeutic window, linker instability, lack of activity, requirement for individualized dosing, or change in business strategy [306–309].

After the drug is released, it diffuses across the lysosomal or endosomal membrane to bind to its intracellular target or leaves the cell through active or passive processes [301,305,310,343]. Depending on their cell permeability, drugs can diffuse across to neighboring cells or, if the drug is released extracellularly, enter nearby cells. For instance, the two forms of auristatin most commonly used, monomethyl auristatin E (MMAE) and monomethyl auristatin F (MMAF), differ in their cell permeability properties. MMAF cannot diffuse across the cell membrane, but MMAE can readily diffuse into the nearby cells and exert its cytotoxic activity, regardless of whether the nearby cells are antigen positive or not—the bystander effect [316,334].

In contrast, drugs attached to noncleavable linkers are usually unable to diffuse across the cellular membrane and so are unable to exert a bystander effect [317,335]. Bystander effects can be beneficial, particularly when targeting solid tumor cells, which can be very heterogeneous in terms of antigen expression [311]. However, the potential benefit of killing all tumor cells has to be balanced with the risk of normal cell toxicity.

An absolute requirement for a successful ADC is that therapeutic concentrations of active drug are achieved and maintained at the target site. The concentration of drug in the target cell is a balance between the amount of drug reaching the cell and the amount of drug leaving the cell. The amount of drug that reaches target cells depends on multiple factors, such as the pharmacokinetic, biodistribution, and plasma stability profiles of the ADC, the drug loading, rate of internalization, efficiency of drug release, efficiency of prodrug activation, and, for non-internalizing ADCs, the rate of diffusion from neighboring cells or the pericellular space. Efflux of drug from the target cells depends mainly on the cell permeability of the drug and on the occurrence of active efflux mediated by drug transporters. The emergence of multidrug resistance (MDR) in tumor cells is an important factor that may limit the

activity of ADCs and is mainly attributed to upregulation of active drug efflux mediated by drug transporters such as the P-glycoprotein (Pgp) [336]. Most cytotoxic drugs (e.g., calicheamicin, doxorubicin, taxanes, maytansinoids, dolostatin 10 derivatives, CC-1065) are good substrates for Pgp, mainly because of their hydrophobicity. Successful approaches to bypass MDR have involved modifying the drug molecule or the linker. For instance, the charged MMAF molecule is a poorer substrate for Pgp than the neutral MMAE [334]. Also, substitution of a hydrazide group with an amide in the linker of a calicheamicin conjugate resulted in greater accumulation in MDR cells [311]. Another approach has been to modify the drugs with hydrophilic noncleavable linkers [336,337]. The more hydrophilic linker–drug compounds demonstrated enhanced retention by Pgp-expressing cells because it is thought that more hydrophilic compounds are poorer substrates for the efflux pumps.

The cytotoxic payload has to be matched with the biology of the target cancer cells. For instance, tubulin-targeting cytotoxic drugs, such as auristatins and maytansinoids, which at the moment dominate the clinical development pipelines, are highly potent against rapidly dividing cells but are less active against slowly dividing cells. This selectivity may contribute to the therapeutic index of ADCs with such payloads by limiting unwanted side effects to toxicities in rapidly dividing healthy cells, which are generally manageable. However, these payloads are inactive against slowly dividing target cells such as tumor-inducing cells (TICs), also known as cancer stem cells (CSCs). DNA-targeting payloads, such as calicheamicin, are more active against slowly dividing cells. On one hand, this makes them better suited to targeting TICs, but, on the other hand, they are generally less well tolerated. A high proportion of the current research efforts in the ADC field are focused on developing new highly potent DNA-targeting payloads such as duocarmycins (Synthon) and pyrrolobenzodiazepine dimers (PBDs) (Spirogen), as well as payloads with a new mode of action for ADCs such as the RNA polymerase inhibitor α-amanitin (Heidelberg Pharma) [298,321,339,344].

***9.4.2.8 Conjugation: Payload Stoichiometry and Stability of Conjugation*** The conjugation site(s), the stoichiometry of drug loading, and the stability of conjugation impact not only the function of the targeting protein molecule but also the aggregation, pharmacokinetic, and biodistribution profiles of the ADC. The effect of drug conjugation on the targeting properties of a drug conjugate has been extensively studied for both albumin [291] and ADCs [145,345–347]. Although a higher drug loading may seem preferable for its potential to achieve higher drug concentrations at the target site, in practice it often has the opposite effect [291,345,347]. The ideal number of drug molecules per antibody appears to be between 2 and 4. It was shown that increasing the drug loading to over 4 per antibody results in higher plasma clearance rates, lower tolerability, decreased efficacy, and actually results in less drug reaching the tumor [347,348].

Most clinical-stage ADCs have an average drug–antibody ratio (DAR) of around 4. However, the two main conjugation technologies currently adopted, namely conjugation to the side chains of solvent-exposed lysine residues (ImmunoGen, Pfizer) or to cysteine residues liberated by reducing the interchain disulfides (Seattle Genetics),

generate heterogeneous mixtures with a broad DAR distribution, generally between 0 and 8. Each DAR species can have its own distinct biological profile with potential differences in efficacy, pharmacokinetics, distribution, immunogenicity, and safety. Moreover, the naked antibody (DAR 0) can act as a competitive inhibitor, limiting the ADC uptake into the target cells and thus potentially reducing efficacy. Mylotarg was a very heterogeneous compound, with an average DAR of between 2 and 3, a DAR distribution of between 0 and 8, and 50% unconjugated antibody [305,321,325]. It is postulated that, in addition to the instability of the acid-labile linker, the high proportion of unconjugated antibody could be a contributing factor to the disappointing results seen for Mylotarg. Interestingly, inotuzumab ozogamicin (CMC-544), another ADC utilizing the same linker-payload and conjugation chemistry, but with a higher average DAR (5–7) and with less than 10% unconjugated antibody, shows very promising clinical efficacy [305,325,326].

Another source of heterogeneity with implications for both efficacy and tolerability is the instability of conjugation. It is well known that maleimide conjugates can undergo retro-addition reactions *in vivo* in the presence of competing free thiols, such as the cysteine 34 of circulating serum albumin [144]. This can lead not only to deconjugation and premature loss of payload from the ADC, but also to cross-conjugation to albumin and the formation of albumin–drug adducts. The clinical implications of maleimide instability are not yet fully understood.

One of the most prominent preclinical stage approaches to overcome the broad DAR distribution of current ADCs is to engineer unpaired cysteine residues at defined locations on the antibody. Conjugation of the drug to the unpaired cysteine residues using maleimide chemistry yields ADCs with homogeneous DAR [147,346,348]. Genentech's THIOMABs is the most advanced technology using engineered unpaired cysteine residues, and this approach is currently being investigated by several other companies, including MedImmune, Seattle Genetics, and Pfizer. Shen et al. [145] showed that the stability of the maleimide linkage and the extent of cross-conjugation to circulating albumin depend on the local environment of the engineered cysteine residue.

The work with THIOMAB ADC variants highlighted the importance of conjugation stability and DAR homogeneity. When examined *in vivo*, the less stable variants were associated with increased off-target toxicity and lower efficacy [145]. Moreover, a homogeneous DAR 2 THIOMAB ADC showed equivalent *in vivo* efficacy and a higher maximum tolerated dose (MTD) compared with a standard ADC with an average DAR of 4 and a DAR distribution of 0 to 8, despite having only about half the amount of drug [145,346,348]. This is an elegant solution to the broad DAR distribution issue but it is not without its limitations. It requires antibody reengineering, which can be time consuming and costly, the engineered cysteine residues can become capped during expression and uncapping can lead to reduction of interchain disulfides and heterogeneous conjugation, and it does not fully solve the issue of maleimide instability.

An alternative approach that avoids the use of maleimide linkers involves conjugation at engineered non-natural amino acids (Ambrx, Allozyne). However, antibody reengineering and expression of variants containing non-natural amino

acids can be complex and expensive. Moreover, the ability to manufacture such ADCs remains challenging as currently reported methods of conjugation require high reagent stoichiometry (up to 30 molar equivalents) and long reaction times (up to 4 days) [349].

***9.4.2.9 Efforts to Control Drug Release*** The potential of ADCs to widen the therapeutic window of small molecule drugs stems from their ability to reduce the systemic exposure of the free drug while increasing the dose of the drug at the target site (i.e., tissue, cells, or both). To achieve this, most ADC strategies incorporate multiple levels of control of drug delivery, often with a cumulative effect on the therapeutic index. However, each such level comes with its own limitations and challenges and has to be tailored to the biology of the target site. The first level of control is given by the targeting mechanism. Passive targeting is nonspecific and has a low degree of selectivity because the majority of the administered dose often accumulates in nontarget tissues [295]. Although active targeting is more selective, it is rarely specific because most antigens are overexpressed rather than uniquely expressed on the target cells [296,297]. Moreover, even for highly specific targeting molecules such as antibodies, the peak concentrations accumulated at the tumor site are less than 0.01% of the administered dose per gram of tumor [303], while the rest of the administered dose remains in circulation or is deposited at nontarget sites.

The second level of control is incorporated in the linker design to achieve selective release of the drug molecule at the target site. The main limitation of cleavable linkers is their plasma instability [305]. Even if the drug is released in circulation at a very low rate, this can cumulate over the many days that most ADCs can remain in circulation. Although noncleavable linkers are very stable in circulation, they are unsuitable for noninternalizing ADCs because they rely on internalization and lysosomal degradation and are also incompatible with bystander effects. Moreover, even when a stable linker is used, drug release in nontarget cells can occur because of antigen-independent internalization through pinocytosis [311].

Strategies to overcome these limitations and reduce toxicity have focused on improving linker stability and on integrating additional levels of drug release control. Double prodrug strategies [305,343] require additional chemical or enzymatic activation steps of the released prodrug at the target site, so even if nondesired release occurs in circulation or at other nontarget sites, the prodrug should have no or reduced toxicity. Other approaches use prodrugs that require photoactivation at the target site (photodynamic therapy) [350] or use thermoresponsive peptide drug carriers that can be activated by locally induced hyperthermia [351].

Alternative approaches to improve ADC therapy may use techniques already established for radioimmunotherapy, such as antibody pretargeting [288,299] and the shielding, sequestration, or removal of antigen-positive nontarget cells before ADC therapy [338]. Another recent approach involved removing the unbound fraction of an ADC from circulation 24 h after administration by extracorporeal affinity adsorption treatment [351]. Such approaches have the potential to optimize the tumor-to-nontumor ratio and thus improve efficacy and reduce toxicity.

## 9.5 PROTEIN MODIFICATION USED FOR DIAGNOSTICS

Diagnostics refers to the process of trying to identify a disease or disorder and usually requires the use of clinical tests. The aim of these tests is to detect or quantify certain biomolecules that are of diagnostic significance or alternatively to identify therapeutic targets for treatment purposes. Proteins, especially antibodies, are particularly suited to this role because of their ability to bind to a wide range of biological targets with unparalleled affinity and specificity. To perform this role, however, proteins often require some form of modification. These modifications can generally be divided into two categories, those allow the antibody detection on binding and those that facilitate their attachment to surfaces. Consequently, antibodies often require the conjugation of different molecular entities such as fluorophores, radiolabels, or even enzymes. These modifications endow the new molecules with new properties that allow them to be used for a wide range of applications from immunohistochemistry (IHC) and immunoassays to imaging and the production of protein microarrays.

Immunoassays are some of the most commonly used diagnostic tools for the analysis of biomolecules, with enzyme linked immunosorbent assays (ELISAs) one of the most currently used immunoassays. The technique first requires the presence of an immobilized ligating reagent, either an antibody or antigen to a solid support, usually a plate surface. An antibody–antigen binding complex is then formed on the addition of its binding partner. After a series of washing steps to remove unbound components, quantification of the successful binding can be evaluated by the addition of a detection reagent or an antibody that is able to bind specifically to the formed complex. Detection requires the conjugation of a measurable label either an enzyme such as horseradish peroxidase or alkaline phosphatase and the subsequent addition of a substrate or the attachment of a fluorophore, such as fluorescein or rhodamine, to the detection antibody. The generated signal can then be quantified and is proportional to the amount of analyte in the sample. ELISA assays have been used diagnostically for the screening and antibody detection in patients with suspected HIV. Hepatitis C infection is also diagnosed by ELISA using antigens to detect antibodies directed against the hepatitis virus [352]. A similar technique, IHC, refers to the process of detecting antigens such as proteins in cells of a tissue section by exploiting the principle of antibodies to bind specifically to antigens present on biological tissues. Again, in this method, the antibodies carry an indicator molecule for their detection and subsequent examination by a microscope. IHC is widely used clinically for the detection of antigens present on abnormal cells such as those found in cancerous tumors. Fluorescently labelled antibodies can also be used to determine cell populations in biological samples. One example of this is the use of antibodies against CD4 and CD8 antigens, which are used routinely to determine the population and of T lymphocytes to follow the progress of patients with AIDs.

Radiolabeled protein-based imaging agents have been particularly useful in the diagnosis and early detection and targeting of certain pathological conditions such as cancer, myocardial injury, and the presence of sites of infection (Table 9.4) [11].

**TABLE 9.4 Protein-Based Imaging Agents [11,347,365]**

| Imaging Agent | Company | Protein Features | Isotope | Clinical Uses |
|---|---|---|---|---|
| Acutect | Diatide, Inc. | Synthetic peptide that binds to GP IIb/IIa on activated platelets | $^{99}$Tc | Deep vein thrombosis |
| Bexxar | SmithKline Beecham | Mouse IgG2a antibody against CD20 | $^{131}$I | Non-Hodgkin lymphoma |
| CEA-Scan | Immunomedics | Mouse IgG1 anti-CEA Fab fragment | $^{99}$Tc | Breast and colorectal cancer |
| Protascint | Cytogen | Mouse IgG1 anti-PSA antibody | $^{111}$In | Metastatic prostate cancer |
| Myoscint | Centocor | Mouse IgG2a Fab against human cardiac myosin | $^{111}$In | Myocardial injury |
| Octreoscan | Mallinckrodt Medical | Labelled octreotide | $^{111}$In | Neuroendocrine tumors |
| Verluma | Boehringer Ingelheim | Mouse IgG2b anti-CEA Fab fragment | $^{99}$Tc | Small cell lung cancer |
| Oncoscint | Cytogen | Mouse IgG1 antibody against the glycoprotein TAG-72 | $^{111}$In | Colorectal and ovarian cancer |
| NeutroSpec | Palatin Technologies | Mouse IgM anti-CD15 antibody | $^{99}$Tc | Appendicitis |
| Zevalin | Spectrum Pharmaceuticals | Mouse IgG1 against CD20 | $^{111}$In | Non-Hodgkin's lymphoma |

CE: carcinogenic antigen; GP: glycoprotein; Ig: immunoglobulin; In: Indium; PSA: prostate-specific antigen; TAG: Tumor Associated Glycoprotein; Tc, technetium.

Several coupling reactions have been devised to attach the radiolabel without blocking the antibody binding site. One such method is to label the antibody via its oligosaccharide chain; an alternative approach is to attach a chelator to the $NH_2$ group of lysine [353].

Heavy metals such as indium and technetium are particularly attractive for this purpose because free isotopes are nontoxic. For imaging purposes, these imaging agents must also possess a high specificity for their target while showing little nonspecific binding to nontarget molecules on healthy tissue (hence why proteins are ideal carriers). Moreover, these molecules must be able to withstand the harsh conjugation conditions required for labeling, and they must be relatively small to localize at the target site quickly and any unbound molecules able to clear from the rapidly body before clinical assessment. Whole antibodies have been used for this purpose, but smaller antibody fragments and peptides are preferred because of their ability to penetrate tumors more quickly while showing a lower circulation half-life that sometimes results in images with improved contrast [354]. Among those that have received FDA approval are capromab pendetide (Prostascint) an indium-111–labeled anti–prostate-specific antigen (PSA) antibody able to recognize intracellular PSA that has been used for the detection of prostate cancer. Apcitude (Acutect)

technetium-labeled synthetic peptide that binds to glycoprotein IIb/IIIa receptors on activated platelets for the imaging of deep vein thrombosis, and Imciromabpentetate (Myoscint), an indium-111–labeled antibody specific for human cardiac myosin used to detect the presence and location of myocardial injury in patients with suspected myocardial infarction [11].

## 9.6 FUTURE DIRECTIONS

There will continue to be many opportunities to improve protein therapeutics. New formulations, such as highly concentrated dosage forms for subcutaneous administration, may require modification to decrease propensities for aggregation. Multifunctional proteins, such as bispecific antibodies are being developed and modifications to optimize each function may become important. Certainly, as non-endogenous proteins are developed, modifications of primary structure will be required to minimize the potential to elicit anti-drug antibodies. Prolonging and optimizing protein half-life is increasingly being recognized as a key property in development. Conjugation of polymers, drugs, and detection moieties will continue because some of the current chemical methods can be made more efficient. Cost of manufacture has not usually been considered a priority, but innovations being made in conjugation modifications so that they can be made earlier in downstream processing may become important. Protein modifications will continue to be developed to optimize formulation properties including maintaining protein stability, utilizing high concentrations and minimizing viscosity. As with all medicines, safety is paramount, and modifications will continue to be developed to make proteins more safe for use in the clinic.

# Analytical Characterization of Proteins and Peptides

YAJUN JENNIFER WANG and BRIAN HOSKEN

## 10.1 INTRODUCTION

The biopharmaceutical manufacturing of therapeutics produces a heterogeneous product composed of populations of structurally related molecules, referred to as product-related variants. The quality and heterogeneity of every protein product is highly dependent on its manufacturing process [1]. This fact has two important implications for the biopharmaceutical industry. First, the manufacturing process must be tightly controlled. After a process has been optimized and locked, changes cannot be made without first assessing the impact on product quality and comparability. The second point, which is the basis for this chapter, is that protein therapeutics must be well-characterized by physicochemical, immunochemical, and biological methods. The definition for a well-characterized biologic was published in the *Federal Register* in 1996 [2]. The concept of a well-characterized biologic was later summarized as "a recombinant DNA-derived protein with known amino acid sequence, disulfide linkages, glycosylation sites, and post-translational modifications. The purity, impurities, and biological activity must be quantifiable and the impurities should be identified" [3,4].

It is often stated that biologics, such as protein therapeutics, cannot be fully characterized because of their complex nature. Although this statement is generally accepted, it should also be acknowledged that advances in bioanalytical techniques and more than 30 years of industry experience with therapeutic proteins are closing the gap between the industry standard of a well-characterized biologic and the goal of a fully characterized biologic [5]. In practice, the extent of characterization is linked to the level of risk associated with each phase of drug development (International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use [ICH] Q9) [6]. For example, although there may not be sufficient time or resources for extensive characterization of a protein therapeutic during early stage development, it is expected that the molecule must

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*,

be well characterized before the Biologic License Application is filed with regulatory agencies.

Protein therapeutics and their variants are characterized and classified by many physicochemical properties, including hydrated size (Stokes radius), molecular weight (MW), charge, hydrophobicity, electrophoretic mobility, isoelectric point (pI), sedimentation velocity, glycosylation, and spectral properties. The nature of each variant can be related to differences in their primary, secondary, tertiary, or quaternary levels of protein structure. Protein variants can be created throughout the biological manufacturing process, which includes the following steps: cell culture, harvest, purification, formulation, and filling into the final container. Some variants may also be introduced during analysis as artifacts. Therefore, product characterization and quality control testing are required at critical points throughout clinical development and manufacturing [7].

This chapter describes the protein therapeutics, including monoclonal antibodies (mAbs), in terms of their expected protein structure and their commonly encountered variants. Current methods and strategies used for the physicochemical characterization of protein therapeutics and their variants will be discussed.

## 10.2 STRUCTURAL CHARACTERIZATION AND CONFIRMATION

The primary structure of a protein therapeutic is its most fundamental property. The amino acid sequence of each protein produced via recombinant DNA technology is known from the vector inserted into each clone. Therefore, the first step in protein characterization should be interrogation of the expected primary structure using widely available software programs. This *in silico* analysis can be used to calculate theoretical MWs, reveal potential glycosylation sites, identify enzymatic cleavage sites, predict hydrophobicity, determine isoelectrical point, compare sequence alignment with other protein products, and identify potential hotspots for unwanted posttranslational modifications.

Variants associated with primary structure (sequence variants) can be attributed to unusual translational events such as the misincorporation of amino acids [8], expression of introns [9], cross-over events [10], or the presence of an uncleaved leader sequence [11]. More commonly, sequence variants are caused by genetic impurities in the cell line. These mutations, which occur during transfection and amplification of the clone [12], can lead to cell lines that produce molecules with varying levels of amino acid substitutions [13]. For this reason, the primary structure of a recombinant protein must be verified to ensure the genetic fidelity of the cell line used to manufacture the pharmaceutical. The following techniques are usually used to verify the amino acid composition and primary structure of therapeutic proteins.

### 10.2.1 Amino Acid Composition by Amino Acid Analysis

Protein amino acid composition and quantitation can be analyzed upon hydrolysis [14]. Several derivatization techniques, such as ninhydrin [15], phenylisothiocyanate

(PITC), 6-aminoquinolyl-*N*-hydroxysuccinimidyl carbamate (AQC) [16], and *o*-phthalaldehyde/9-fluoromethyl-chloroformate (OPA/FMOC) [17], with either precolumn or postcolumn derivatization, have been used. Direct analysis of amino acids using the integrated pulsed amperometric detection (IPAD) method is also possible. The liberated amino acids are separated using reversed-phase high-performance liquid chromatography (RP-HPLC), ion-exchange chromatography (IEC), or capillary electrophoresis (CE). Recently, methods that combine AccQ·Tag chemical derivatization with the exceptional chromatographic resolution of ultra-high-performance LC (UHPLC) [18], and in conjunction with the high sensitivity and selectivity of tandem mass spectrometry (MS/MS) were reported [19].

Free amino acid composition and their levels in the cell culture media are analyzed directly. Another example of amino acid analysis is the detection and quantification of nor-Leucine misincorporation for methionine during *Escherichia coli* fermentation processes [15].

### 10.2.2 Amino Acid Sequence via N-Terminal Sequencing

N-terminal sequencing via Edman degradation [20] was routinely used to confirm the protein amino acid sequence until tandem LC–MS was introduced more than a decade ago. N-terminal sequencing still has its value as an identity method to distinguish isobaric amino acid residues, such as Leu/Ile and deamidation product isoaspartate (isoAsp) or aspartic acid (Asp), and to provide complementary sequence information along with MS/MS [21].

### 10.2.3 Peptide Mapping via Tandem Liquid Chromatography–Mass Spectrometry

Peptide mapping is the main tool for confirming the primary structure of proteins and identifying sequence variants. The general procedure for generating a peptide map is to denature, reduce, alkylate, and digest the protein with a highly specific protease. The resulting peptides are separated and profiled by RP-HPLC with ultraviolet (UV) detection [8,22,23]. A recent article described the optimization of peptide maps for mAbs with emphasis on reducing sample preparation time and eliminating artifacts [24].

An early example of the identification of a sequence variant by peptide mapping was reported by Harris et al. in 1993 [12]. A combination of techniques (amino acid analysis, N-terminal sequencing, and MS) was used to identify every peak in the chromatogram, resulting in 98% coverage of the antibody. The mutation, which occurred in 21% of the heavy chain, was also confirmed at the DNA level with a polymerase chain reaction (PCR) assay. The sequence variant detection sensitivity improves with the use of modern MS. It has been reported that a comparison of UV peptide map chromatograms only allows the detection of sequence variants occurring at a frequency greater than 3% [25]. With MS/MS detection, peptide maps are capable of resolving and quantifying low-level variant peptides that co-elute with more abundant peptides. Under some circumstances, the LC/MS/MS analysis of

peptide maps can enable the identification of sequence variants occurring with a frequency as low as 0.01% [26]. A workflow for identifying posttranslational modifications and amino acid substitutions from high-resolution and mass accuracy LC/MS/MS instruments has recently been described [27]. Demonstrating the absence of sequence variants in a therapeutic antibody requires a significant amount of time and highly skilled analysts. A systematic analytical approach combining tryptic and chymotryptic peptide mapping with a mascot error tolerant search (ETS) has been developed to detect and identify low-level protein sequence variants in recombinant mAbs [25].

### 10.2.4 Protein Identity by Matrix-Assisted Laser Desorption/Ionization–Mass Spectrometry Peptide Mass Fingerprinting

Peptide mass fingerprinting (PMF) was first described and demonstrated with fast atom bombardment MS by Henzel et al. 1989 [28]. Despite its promise, the method was seldom used until 1992, with the coming of significantly more sensitive commercial instrumentation based on matrix-assisted laser desorption/ionization–time-of-flight–mass spectrometry (MALDI-TOF-MS). Since then, the method grew from a need for a faster, more efficient method to identify frequently observed proteins in electrophoresis gels. PMF laid the foundation for high-throughput, high-sensitivity methods of protein analysis, now known as proteomics [29]. PMF is now being used routinely as a protein identification method in therapeutic protein product manufacturing because of its high specificity and fast analysis time. The method can be validated per ICH guideline Q6B [4] for identity testing.

### 10.2.5 Sulfhydryl Group(s) and Disulfide Bridges

Characterization at the secondary and tertiary levels of protein structure often focuses on the many intra- and intermolecular disulfide bonds. Disulfide bonds in the antibody hinge region are difficult to assign because of closely spaced cysteines. The analysis of disulfide-linked peptides containing multiple cysteine residues by N-terminal sequencing and LC/MS allows for the unambiguous assignment of disulfide linkages [30]. The complete set of disulfide bond linkages was assigned for an IgG4 molecule using a strategy that involved LC/MS/MS analysis of reduced and nonreduced Lys-C digests [31].

Disulfide variants related to incorrect disulfide linkages can be unique to specific IgG isotypes. For example, IgG4 antibodies have a tendency to form intramolecular disulfides in the hinge region [32]. The result of this modification is an intact antibody held together by noncovalent interactions. The relative percentage of noncovalently bound antibodies (i.e., noncovalently bound light chain and heavy chain) can be measured by denaturing methods such as sodium dodecyl sulfate (SDS)–capillary gel electrophoresis [33]. IgG2 antibodies have a tendency to form intermolecular disulfide bonds between the hinge regions and the light or heavy chains [34]. These mixed disulfides produce structural isoforms that have been separated by electrophoresis, reversed-phase and IEC [34–35].

There are also unusual variants related to the loss or addition of a sulfur atom in disulfide bonds. A nonreducible thioether bond has been identified in IgG1 molecules [36]. This cross-link occurs between the heavy (Cys-223) and light chain (Cys-213) after the loss of a sulfur atom. A decomposition pathway involving β-elimination has been proposed [37]. Recently, the existence of trisulfide bonds in the hinge of an IgG2 mAb has been reported [38]. This modification is unusual in proteins and may be a result of the fermentation process.

Every cysteine residue in the antibody should be engaged in an intra- or intermolecular disulfide bond. Although intramolecular disulfides are not required for the correct protein conformation, they do have a stabilizing effect on the tertiary and quaternary structure of the antibody [39,40]. Therefore, it is expected that the presence of unpaired cysteines could lower the thermodynamic stability of the molecule. A free thiol variant could affect product quality during storage and limit the shelf life of the therapeutic antibody. The thiol side chain on an unpaired cysteine residue is very reactive and could be a potential source of product heterogeneity. For example, cysteinylation of an unpaired thiol in a mAb has been identified by LC/MS analysis of the Fab region [41]. Free sulfhydryls have also been demonstrated to reduce the potency of a therapeutic antibody [42]. Free thiols are typically assayed with Ellman's reagent [43], although a fluorescence method for measuring unpaired cysteines has also been developed [44].

### 10.2.6 Carbohydrate Structure

The glycosylation of proteins occurs during and after translation and involves multiple glycosyltransferases and glycosidases. The resulting oligosaccharide structures are complex and highly dependent on the expression system and cell culture conditions. Although glycoproteins may have many different forms of glycan structures at either O-linked or N-linked sites (or both), all IgG antibodies contain a single, N-linked, glycosylation site in each of the CH2 domains of the Fc region. In addition, 15 to 20% of naturally occurring polyclonal antibodies and one licensed therapeutic antibody also contain an additional glycosylation site in the Fab regions [45]. When expressed in hamster or mouse cell lines, the Fc sites of recombinant antibodies are occupied by oligosaccharide structures similar to those found in the human population. The dominant glycan species are related to a common biantenary, core-fucosylated structure with the addition of zero (G0), one (G1), or two (G2) terminal galactoses. In addition to the major glycan species, there are many minor species related to incomplete processing or the presence of additional sugars on the terminal galactose. Common glycan species observed in recombinant mAbs expressed in mammalian cell lines and their corresponding mass are shown in Table 10.1.

Glycosylation is essential for the proper structure and function of antibodies [46]. The effects of certain glycan structures or the absence of glycans on the biological activity of therapeutic antibodies is well established and has been thoroughly reviewed [47,48]. For example, the absence of core fucose or the presence of terminal galactose increases certain effector functions of antibodies. Glycosylation is a critical attribute of therapeutic antibodies whose mode of action involves cell

**TABLE 10.1 Typical N-Linked Glycans on Recombinant Monoclonal Antibodies**

| Structure | Abbreviation | Average Mass (Da) of N-Linked Glycans [M-18]* | Average Mass (Da) of Released Glycans $[M+Na]^+$ |
|---|---|---|---|
|  | Man5 | 1217.1 | 1258.1 |
|  | G0-GlcNAc | 1242.1 | 1283.1 |
| | G0-Fuc | 1299.2 | 1340.2 |
|  | G0 | 1445.3 | 1486.3 |
|  | G1/G1′ | 1607.5 | 1648.5 |
|  | G2 | 1769.6 | 1810.6 $[M-H]^-$ |
|  | G1+SA | 1898.7 | 1915.7 |
|  | G2+SA | 2060.8 | 2077.8 |
|  | G2+2SA | 2352.1 | 2369.1 |

*Dehydrated masses (M−18) are useful for identifying glycans on peptides and proteins by liquid chromatography–mass spectrometry. The masses of released glycans ($[M+Na]^+$ or $[M-H]^-$) are used to identify glycans by matrix-assisted laser desorption/ionization analysis. ◯ Fucose (Fuc), □ mannose (Man), ▲ GlcNAc, ■ galactose (Gal), ◇ sialic acid (SA).

killing through effector functions. Glycosylation may also pose a safety concern. Antibodies produced in mammalian cell lines can incorporate non-human and potentially immunogenic sugars [49]. For example, whereas murine cell lines add *N*-glycolyl neuraminic acid (NGNA), native human antibodies contain only *N*-acetyl neuraminic acid (NANA). Oligosaccharide linkages can also vary among species. Mouse cell lines are also capable of producing galactose-α-1,3-galactose

(α-Gal), but humans lack the necessary glycosyltransferase to make this linkage. The Gal-α-1,3-Gal disaccharide present in the Fab portion of a therapeutic antibody has been linked to immune responses in patients [45]. Because glycosylation can affect the efficacy, pharmacokinetics (PK), and safety of mAbs and protein therapeutics in general, it is necessary to perform a thorough characterization of their carbohydrates. Because of the complex nature and heterogeneity of oligosaccharides, detailed characterization may require multiple analytical techniques.

Glycans can be characterized at several levels of detail. The most basic analysis involves hydrolyzing the oligosaccharide into its individual sugars. Compositional analysis is used to determine the relative percentage of carbohydrates present on the antibody and to determine the concentrations of individual monosaccharides. The next level of analysis involves profiling the intact glycans released from the protein. The highest level is glycosylation site profiling. This type of analysis requires protein digestion and separation of the glycopeptides before glycan profiling. Because compositional analysis provides little information and glycosylation site profiling is not required for typical antibodies, the focus of this review is on glycan profiling of the Fc region of mAbs. Glycan profiling techniques can be further divided into those that are used for the characterization of enzymatically released glycans and those that are applied to the characterization of the intact, reduced, or digested antibody containing bound glycans.

***10.2.6.1 Analysis of Released Glycans*** The analysis of released, N-linked glycans usually requires several labor-intensive and time-consuming steps. Glycans must first be released from the antibody, purified to remove the proteins, and derivatized with a fluorescent dye for detection purposes [50] and then frequently purified again to remove the free dye before separation by chromatography or electrophoresis. Glycans can be released from the antibody by chemical or enzymatic methods. Hydrazinolysis completely removes N-linked glycans from proteins [51]; however, this method uses hazardous chemicals and degrades the protein [52]. Enzymatic approaches are more commonly used for antibodies because they typically contain only N-linked glycosylation sites, and the only protein modification from digestion is deamidation of the asparagine (Asn) glycosylation site [53]. Most protocols use the endoglycosidase peptide-N-glycosidase F (PNGase F) because this enzyme cleaves the amide bond between Asn and the first GlcNAc [53]. Methods for the enzymatic release of glycans from protein in solution or bound to polyvinylidene fluoride (PVDF) membranes have been described [54,55]. Both chemical and enzymatic methods for oligosaccharide release create an intact glycan with a reducing terminus (aldehyde functional group) that can be derivatized through the process of reductive amination with fluorescent probes containing aromatic amines [50]. Fluorescent detection provides the relative molar concentrations of each glycan because each structure has a single label at its reducing end.

***10.2.6.2 High-Performance Liquid Chromatography Profiling of Glycans*** HPLC profiling of fluorescently labeled glycans provides both high resolution and sensitivity. Critical steps of this analysis (oligosaccharide release, selection

of fluorescent probes and derivatization chemistry, purification methods, modes of chromatography) and strategies for sequence determination have been reviewed [56,57]. With regard to mAbs, most separations are performed using normal phase chromatography with amide or amine functional groups on the stationary phase [58–61]. Amide columns separate glycans by hydrophilic interactions (HILIC), which increase with the size of the glycan structure. Amine columns provide a mixed-mode separation based on the charge and hydrophilicity of the oligosaccharides. UHPLC separation of released glycans in HILIC mode was compared with reversed-phase (RP) and porous graphitic carbon chromatography (PGC) modes. The high selectivities, as well as the commercial availability of ultra-high-performance stationary phases render HILIC the chromatography method of choice for the analysis of glycans [62]. Nonlabeled oligosaccharides can be separated by high pH anion exchange chromatography with pulsed amperometric detection (HPAEC-PAD) [63,64]. Although not as sensitive as methods using fluorescent detection, HPAEC-PAD has the benefit of much simpler sample preparation.

The identification of chromatographic peaks is typically determined by comparing the retention times of unknown peaks to those of known standards or by performing sequential digestions with highly specific exoglycosidases [65]. Unknown peaks can also be identified by fraction collection and off-line MS analysis [66]. The use of an LC/MS system allows for the direct identification of glycan species. For example, glycans from a recombinant IgG have been labeled with 2-aminobenzamide (2-AB), separated by reverse phase ($C_{18}$) chromatography and analyzed by electrospray ionization (ESI)/MS [67,68].

***10.2.6.3 Capillary Electrophoresis Profiling of Glycans*** Electrophoretic techniques are capable of providing separations similar to HPLC with higher resolution in less time. The evolution of electrophoretic methods for glycan profiling, from paper to capillary electrophoresis, has been reviewed [69]. Capillary electrophoresis with laser-induced fluorescence (CE-LIF) detection is a viable alternative to chromatography methods because of its high resolution, sensitivity, and speed. Separations can be completed in 5 to 25 minutes depending on the protocol. The separation and detection of neutral oligosaccharides requires derivatization with a charged fluorophore such as APTS (8-aminopyrene-1,3,6-trisulfonic acid) [70,71] or 2-AA (2-aminobenzoic acid) [72]. With each glycan carrying the same charge at its reducing terminus, differences in mobility are related entirely to differences in the hydrated volume of each structure. This mechanism permits the complete resolution of both structural isomers related to the presence of a single terminal galactose (G1 and G1′).

Identification of glycan species in the electropherogram is usually determined by comparing the migration time of unknown peaks to those of oligosaccharide standards or by performing sequential digestions of oligosaccharide samples with specific exoglycosidases. Another strategy for characterizing CE glycan profiles involves first purifying the labeled oligosaccharides by HPLC, identifying them by offline MS, and then analyzing the known glycan species by CE-LIF [72]. Overcoming the challenges of coupling CE to MS has made it possible to directly

characterize the CE profiles. Recently, a CE-LIF method was modified and coupled to an ESI-TOF MS to characterize unknown glycan species observed during routine CE-LIF profiling [73,74].

***10.2.6.4 Mass Spectrometry Profiling of Released Glycans*** Released glycans are also characterized by MS techniques. Labeled glycans contain the necessary charge for detection, but unlabeled, neutral glycans are detected in the positive mode as adducts of alkali metals. Sialylated glycans can be detected in the negative mode [54]. For mAbs produced in well-characterized expression systems, the MW information from MALDI is usually sufficient to identify glycan species. Confirmation of the linear sequence and linkages requires a more complicated ESI-MS/MS analysis. A multimethod strategy for the complete structural characterization of 2-AA labeled glycans released from the Fc and Fab sites of a therapeutic antibody has been described [66]. Normal phase HPLC, MALDI/MS, sequential enzymatic digestion, and MS/MS fragmentation were used to identify 21 oligosaccharide structures. The sequence and linkages were defined by the activity of highly specific exoglycosidases and MS/MS fragmentation patterns.

***10.2.6.5 Glycan Profiling of Intact, Reduced, and Digested Monoclonal Antibodies*** Glycan profiling can also be accomplished by the LC/MS analysis of intact, reduced, or digested antibodies. The performance and limitations for each approach have been reviewed [75]. Analysis of the intact antibody has the benefit of requiring very little sample preparation. However, the resolution is limited by several factors: (1) the high MW of the intact antibody, (2) molecule heterogeneity, and (3) broad isotopic distribution. Analysis of the reduced or papain-digested antibody provides higher mass resolution as a result of the lower MW and less heterogeneity. Another benefit of the LC/MS analysis of papain digested antibodies is that the physical separation of the Fab and Fc portions allows for the site specific profiling of mAbs with an additional glycosylation site in the complimentary determination regions (CDR) [76]. The performance of LC/MS for quantifying glycoproteins and glycopeptides from five different sample preparations (intact IgG, Fc fragment, HC, HC Fc fragment, and the tryptic peptide) was recently compared with N-glycan HPLC profiling. LC/MS analysis of the HC Fc fragment gave comparable results in terms of the number of glycans identified and their relative concentrations to the standard HPLC profiling method [77].

## 10.3 PHYSICOCHEMICAL PROPERTIES

### 10.3.1 Molecular Weight (or Size)

Molecular weight (or size) is one of the fundamental physicochemical properties of proteins. Size profiling analytical techniques includes size exclusion chromatography (SEC) with light scattering detection, ultracentrifugation, electrophoresis, and MS. These techniques are summarized in this section.

***10.3.1.1 Size Exclusion Chromatography*** Size exclusion chromatography is the simplest and most routinely used technique in the biopharmaceutical industry for measuring size heterogeneity. Size variants, including high-molecular-weight aggregates and low-molecular-weight fragments, are separated from the intact proteins by differences in their hydrated sizes (Stokes radius). Proteins diffuse in and out of pores in the stationary phase at rates that depend on their hydrated size. The differences in diffusion rates are measured by the volume (or retention time) required for each variant to elute from the column. The elution volume of each variant can be used to calculate its relative MW compared with those of protein standards with a known MW and Stokes radii.

Size exclusion chromatography is widely used throughout industry for many reasons. HPLCs are standard equipment, and this technique has few parameters (column, flow rate, mobile phase, and protein load) to optimize. SEC can also be performed under denaturing conditions (dSECs) to measure size variants that are noncovalently associated and therefore undetectable under native conditions [78].

Size exclusion chromatography has several limitations, such as relatively low resolution. Although SEC can be used to quantify irreversible and slowly dissociating aggregates, fast-dissociating aggregates may not be observed because of dilution that occurs during sample preparation and chromatography. This implies that the measured aggregate profile may not accurately reflect the aggregate profile of the formulated proteins. The separation can also be affected by nonspecific interactions between the protein and column. These types of interactions lead to broad peak shapes, delayed elution volumes, and poor column recovery. The nature of protein–column interactions and the importance of mobile phase composition has been reviewed [79].

***10.3.1.2 Light Scattering*** The addition of refractive index and multiangle laser light scattering (MALLS) detectors to the SEC HPLC system allows for the simultaneous determination of aggregate concentrations and absolute MWs [80–82].

The MW value obtained from static light scattering is considered absolute because it is calculated directly from the measurement using equations derived from first principles and does not rely on size standards. Accurate MW calculations depend on well-resolved species. The refractive index and light scattering detectors must also be calibrated before the analysis. Light scattering detectors are very sensitive to higher order aggregates, making this analysis suitable for measuring the removal of aggregates during purification steps [83] and for measuring product stability [82].

Dynamic light scattering (DLS) measures the diffusion coefficient of proteins in solution. The measured diffusion coefficient can then be related to the hydrated diameter of a protein by the Stokes–Einstein equation. DLS measurements are simple and fast because they do not require calibration, and it is only necessary to know the temperature, refractive index, and viscosity of the solution. Another benefit is that measurements can be made under conditions that are more representative of the formulated antibody. Similar to static light scattering, accurate size determinations are only possible for homogenous protein solutions. Applications for DLS in

the pharmaceutical industry include rapid determination of size homogeneity, measurement of thermal stability of antibodies, and online characterization of size variants from SEC [84]. This technique has also been used to study the effect of aggregation and protein concentration on the opalescence of antibody formulations [85] and to demonstrate the removal of size variants by successive purification steps [83].

***10.3.1.3 Analytical Ultracentrifugation*** Analytical ultracentrifugation (AUC) provides absolute MWs under sedimentation equilibrium conditions. A protein solution reaches equilibrium in a centrifuge when the sedimentation force from radial acceleration is countered by the opposing force of diffusion. The equilibrium concentration profile can be fit to an exponential equation that provides the MW of the protein. As with light scattering measurements, a sedimentation equilibrium experiment only provides a true MW value for a homogenous protein solution and therefore has limited applications for the characterization of protein variants.

Sedimentation velocity (or moving boundary) is a second type of AUC experiment that is more relevant to the characterization of therapeutic antibodies [86,87]. Sedimentation velocity experiments are performed at higher rotor speeds than sedimentation equilibrium experiments to overcome the opposing diffusion force. Under these conditions, each size variant sediments at a velocity that is dependent on its MW and hydrodynamic properties. The concentration profile is measured at intervals throughout the separation and then deconvoluted to yield sedimentation coefficients and relative amounts for each size variant.

Sedimentation velocity experiments provide information similar to SEC with good agreement [88]. SEC separations provide better sensitivity for low levels of aggregates. However, the limit of quantitation for AUC has been separately reported to be 0.6% of aggregates [89,90]. For the characterization of complex aggregate profiles, sedimentation velocity experiments have several key advantages over SEC separations. AUC provides higher resolution across a larger range of protein sizes. More important, AUC experiments are performed on a homogenous solution without prior separation or preparation, which eliminates the artifacts sometimes observed during chromatography. AUC experiments can be performed under many different solution conditions, including pH, protein concentration, ionic strength, and temperature. This benefit allows the characterization of aggregate profiles under conditions that are more representative of the formulated product. Despite these advantages, AUC is not widely used for the routine characterization of antibodies. Factors limiting its use include the requirement of specialized instrumentation, complicated data analysis, and the requirement of highly trained personnel.

***10.3.1.4 Electrophoresis*** Gel electrophoresis is an established method for measuring size variants under denaturing conditions. This analysis resolves fragments, which are only held together by noncovalent interactions and are therefore undetected by SEC. Although there are now several platforms for performing electrophoresis, the separation principles remain the same. In the presence of SDS, proteins obtain a constant mass-to-charge ratio that enables their separation in a molecular sieving matrix under the influence of an applied electric field.

The smaller proteins migrate through the gel faster than the larger ones. Within the pharmaceutical industry, the standard polyacrylamide slab gel format (SDS-PAGE) has been largely replaced by capillary electrophoresis in a gel-filled capillary (CE-SDS) for several reasons. First, the CE instrument is fully automated in contrast to the labor-intensive SDS-PAGE analysis. Second, UV or LIF signal near the capillary outlet is recorded digitally. Online detection eliminates the staining, destaining, imaging, and densitometry steps required for slab gel analysis. Third, the analytical performance of CE-SDS is better than that of SDS-PAGE with regards to accuracy, precision, and dynamic range. Both methods can have comparable sensitivity depending on the staining and detection methods.

CE-SDS methods have been developed for both UV [33,91,92] and fluorescence detection [93–97] strategies. Fluorescence detection requires that the antibody sample first be derivatized with a fluorescent probe. This labeling step complicates sample preparation and adds the possibility of introducing an artifact. However, the sensitivity of the method is greatly increased. The 3-(2-furoyl)-quinoline-2-carboxaldehyde (FQ) dye fluorescence method takes the advantage of nonfluorescing free dye so that it does not need to be removed after labeling [94,97]. Fluorescent probes and labeling strategies for CE can be found in a review by Lacroix et al. [98].

Gel electrophoresis has also been adapted to microfluidic devices [99]. Applications of this technology for protein analysis have been described in several reviews [100–102]. The suitability of microchip electrophoresis (MCE) with commercially available instrumentation and chips has been demonstrated for the sizing and quantitation of antibody size variants [103–105]. This format has all the advantages of CE-SDS with one major distinction. The separation of antibody size variants can be performed in a fraction of the time as a result of the much shorter separation distance. The analytical performance of MCE has been compared with that of conventional CE-SDS with UV detection. The chip format was 70 times faster and had comparable resolution, precision, and sensitivity [106].

***10.3.1.5 Liquid Chromatography–Mass Spectrometry*** As the first step of protein structural characterization, the mass of intact or reduced molecules is usually determined using MS. Modern instruments can determine the mass of a mAb to a mass accuracy of close to 10 ppm ($\sim$1.5 Da) [107].

Theoretical considerations include instrument resolution, mass accuracy, and mass range. An ideal instrument for mass determination of intact mAbs should have a resolution of 8000 to 10,000, a mass accuracy in the mid-ppm range, and an m/z range of up to 5000 for ESI, and 175,000 for MALDI [107]. The first successful attempts for mass determination of intact antibodies with reasonable accuracy were performed using MALDI-TOF instrumentation or ESI with a quadrupole mass analyzer. However, the method of choice today for accurate mAb mass determination is by LC–MS on an ESI-TOF or ESI-Q-TOF instrument [108].

To increase the throughput of mass determination, coupling LC directly to the mass spectrometer becomes necessary. However, analytical characterization of therapeutic proteins, especially mAbs, had been hindered for a long time by the lack of appropriate chromatographic methods to be used in conjunction with

high-resolution MS. Those methodologies for standard RP–HPLC, especially the RP-chromatographic resins, are incompatible with antibodies because of irreproducibility, low recovery, short column lifetimes, and poor resolution of degradation products. Improved analytical RP-HPLCMS methods were developed for monitoring and characterizing recombinant proteins [109], intact antibodies [108], reduced antibodies [110], human antibody IgG2 domains [111], and limited digested Fc-fusion proteins [112].

Another challenge for MS analysis of chromatography using a salt mobile phase, such as IEC and SEC, is the incompatibility of subsequent detection. However, by modifying the mobile phase with the MS detection to exclude salt, the method becomes compatible with MS for LC–MS analysis of large proteins, with some sacrifice in chromatography resolution. To enable the MS detection from typical LC separations, Alvarez et al. demonstrated a generic online LC–MS method operated in a two-dimensional format for the rapid characterization of mAb charge and size variants [113]. Using a single chromatographic system capable of running two independent gradients, up to six fractions of interest from a size exclusion (SEC) or an ion exchange (IEC) separation can be identified by trapping and desalting the fractions onto a series of reversed phase trap cartridges with subsequent online analysis by MS. An online disulfide reduction step was successfully incorporated into the workflow, allowing more detailed characterization of modified mAbs by providing chain-specific information.

### 10.3.2 Extinction Coefficient

The extinction coefficient of a biological product is one of the physicochemical properties that ICH Q6B requires to use if UV absorption is used to measure protein content [4]. The mass extinction coefficient ($E^{0.1\%}$, referred to as extinction coefficient) represents the absorbance of a 1 mg/ml or 0.1% mass/volume protein solution in a 1-cm cuvette. The extinction coefficient can be predicted based on the amino acid composition of the protein under the experimental conditions [114,115], experimentally determined via amino acid analysis [15,116], or both.

Formulation changes can have an effect on protein absorbance and should be considered. Protein UV absorbance is partially dependent on the ionization state of tyrosine residues. Because the $pK_a$ of tyrosine is about 10, the extinction coefficients of all formulation buffers below pH 8 are considered equivalent. At a pH above 8, differences in pH can affect absorbance significantly. Therefore, if the formulation pH changes across pH 8, the experimental extinction coefficient must be redetermined with the new formulation.

### 10.3.3 Charge Profiling

Therapeutic proteins are also characterized by differences in their charge states (i.e., net charges at a certain pH). Charge profiling of intact proteins, under native conditions, can resolve variants related to protein conformation, size, sequence variants, glycosylation, and posttranslational modifications. Charge profiling

methods are an integral component of characterization studies and quality control strategies because they are sensitive to many types of modifications.

Ion-exchange chromatography and isoelectric focusing (IEF) are widely used to characterize proteins within the pharmaceutical industry. These two charge profiling methods and the commonly observed modifications have been thoroughly reviewed [117]. Both techniques use very different separation mechanisms and may or may not provide complementary information. Whereas IEC is based on electrostatic interactions between the stationary phase and charged groups on the protein surface, IEF separations are based on differences in the overall net charge of the protein isoforms.

***10.3.3.1 Ion-Exchange Chromatography*** Ion-exchange chromatography separations are developed by choosing a cation or anion exchange column and varying the buffer system, pH, and ionic strength of the elution buffer. IEC of mAbs is typically performed with a weak cation exchanger (WCX) and salt gradients [118]. However, a recent publication described the optimization of a pH gradient IEC method for the separation of mAb charge variants [119]. IEC separations are popular within the industry because they use commonly available and reliable HPLC instruments and perform consistently. IEC profiles are also amenable to characterization because fractions can be collected from analytical or preparative scale separations and subjected to downstream analysis (e.g., LC/MS, peptide mapping, potency, N-terminal sequencing). A strategy for the assignment of peaks from a WCX separation has been published [118]. One negative aspect of IEC is that method development can be labor intensive and is usually specific for each protein product. On the other hand, IEC separation based on pH-gradient elution correlates well with proteins' pI, thus allowing for the development of generic separation conditions that can be applied to many therapeutic proteins [119].

***10.3.3.2 Isoelectric Focusing*** Isoelectric focusing is a high-resolution technique that can separate protein isoforms with very minor differences in their pI. Under the influence of an electric field, charge variants migrate through a pH gradient until they reach a position in which they have no net charge. IEF separations can be performed in gels with immobilized pH gradients or in capillaries with self-forming gradients. Both formats work well, but IEF gels have been replaced with capillary IEF (CIEF) for the same reasons that SDS-PAGE has been replaced by CE-SDS. Automation is not possible with gels, and CIEF is more quantitative because of the on-capillary detection. Examples of the development and validation of CIEF methods for mAbs have been published [120–122].

Recently developed imaged capillary isoelectric focusing (ICIEF) technology uses a different capillary format. The separation takes place in a short, transparent capillary that enables detection by a digital camera. The short focusing distance and lack of a mobilization step reduce the analysis time of ICIEF. Method development and validation of ICIEF methods for therapeutic mAbs have also been described [123,124].

Capillary IEF methods offer several benefits compared with IEC. They are typically faster, provide higher resolution, and can be generic for many different

antibodies. A significant drawback of CIEF methods is that they require specialized instrumentation, and the charge profiles are difficult to characterize because of the nanoliter separation volumes (i.e., fractions are difficult to collect). IEC fractions have been collected, characterized, and analyzed by ICIEF in an effort to characterize the charge profile and correlate the two different separations [124]. A better approach to characterizing CIEF charge profiles is to use a preparative IEF technique. Several different platforms for preparative IEF exist [125]; however, there are few examples of the application of preparative IEF methods for the characterization of mAb charge isoforms [126,127].

### 10.3.4 Hydrophobicity Profiling

HPLC is one of the most frequently used techniques for characterization of biotherapeutics. Besides SEC and IEC methods mentioned earlier, other commonly used chromatographic profiling methods include RP [128] and hydrophobic interaction chromatography (HIC) [129,130].

Reduced RP chromatography has been a popular method for the characterization and identification of clips and variants [128]. Stackhouse et al. [128] have developed a high-throughput UHPLC method with a 1.7-μm phenyl column. This UHPLC method allows quantitation of hinge clipping in an IgG1 molecule and acid-induced Asp/proline (D/P) clip in an IgG2 molecule. The results from the UHPLC method were comparable to those obtained with reduced CE-SDS. Additionally, the phenyl column offered partial resolution of oxidation and other chemical modifications, making this technique an attractive method for high-throughput process characterization and formulation screens.

Valliere-Douglass et al. [129] described the use of HIC to separate and characterize variants of mAbs resulting from variable N- and C-terminal processing, stress-induced covalent modifications, and conformationally altered populations. Boyd et al. presented a case study using HIC to separate an oxidized Trp-containing variant, oxidized methionine (Met) and isomerization/deamidation variants in an IgG1 [130].

## 10.4 BIOPHYSICAL PROPERTIES (HIGHER ORDER STRUCTURE AND STABILITY)

Biophysical techniques such as circular dichroism (CD), second-derivative UV spectroscopy, differential scanning calorimetry (DSC), Fourier-transform infrared spectroscopy (FTIR), AUC, and fluorescence spectroscopy are used to measure the higher order structure of proteins. Because these methods are well suited to measuring changes in protein structure and conformation relative to an initial condition, they are useful for measuring antibody stability in different formulations or conditions [131,132]. These biophysical techniques are not commonly applied to the routine characterization of mAbs because they are not sensitive to small structural changes that may only occur in a small fraction of the population. There are, however, many published examples of the application of biophysical techniques

to the structural analysis of enriched populations of antibody variants. Some examples follow:

- Analytical and biophysical (CD, tryptophan fluorescence, DSC) techniques were used to demonstrate that modification of a cysteine residue in the CDR region resulted in changes to the tertiary but not secondary structure of an antibody [133].
- CD and second-derivative UV spectroscopy were used to demonstrate that an IgG1 dimer had identical secondary structure compared with the monomer [134].
- Differences in the tertiary structure of IgG2 disulfide isoforms were observed by AUC, DSC, and CD experiments [135].
- CD data linked decreased stability with increased aspartate isomerization in two closely related antibodies. X-ray crystallography was also used to demonstrate that solvent accessibility increased Asp reactivity [136].
- Aggregation of a therapeutic antibody was characterized by light scattering, CD, and fluorescence spectroscopy [137].
- FTIR analysis of mAb particles that were generated by agitation indicated that the secondary structure was relatively unchanged from the native mAb [138].

## 10.5 OTHER POSTTRANSLATIONAL MODIFICATIONS AND PRODUCT-RELATED IMPURITIES

Other than glycosylation, common modifications observed in therapeutic IgGs include N-terminal glutamine (Gln) conversion to pyroglutamic acid (pGlu) [139–142], C-terminal Lys enzymatic processing [143] and C-terminal amidation [144], deamidation and isomerization [118,145–148], oxidation [110,135,149–154], and glycation [155–161]. This section reviews these common posttranslational and chemical modifications and the analytical methods used for their separation, detection, and structural elucidation.

### 10.5.1 N-Terminal Pyroglutamic Acid Formation

It is well known that the N-termini of mAbs can be modified through acetylation, formylation, and pyroglutamylation [162]. Among these, pGlu formation is of special interest because most mAbs have Gln or glutamic acid (Glu) at their N-terminus. There are three key suggestions in the literature as to the origin of this N-terminal variant, namely (1) enzyme glutaminyl cyclase in the cell culture process [140,163–166], (2) nonenzymatic spontaneous conversion [142], and (3) analytical artifacts [110,142]. The enzymatic reaction in the cell culture process plays a major role, leading to the most conversion. In the nonenzymatic case, the pseudo first-order reaction is driven by the formation of a product with a relatively stable five-member ring structure and the release of ammonia (Fig. 10.1). The

**FIGURE 10.1** Mechanism of formation of pyroglutamic acid from N-terminal glutamine.

reaction rate depends on temperature; pH; and, to a lesser extent, conductivity. Certain buffers, such as phosphate, may act as catalysts to increase the pGlu formation rate. The conditions presented in most biopharmaceutical processes can accelerate the formation of this variant. Therefore, nearly complete conversion (>95%) of N-terminal Gln to pGlu is commonly observed for some antibodies. N-terminal Gln may also convert to pGlu as an assay artifact. Rehder et al. [110] measured the N-terminal pGlu conversion of a degraded IgG1 using tryptic and Glu–C peptide map analyses by LC–MS, and his data suggested that N-terminal Gln may convert to pGlu during peptide map analysis, which is typically conducted at a pH of 7.5 and 37°C. This condition facilitates the formation of pGlu on the N-termini of unfolded peptides. Therefore, to accurately quantitate the content of pGlu/Gln species, an analytical strategy has to be carefully designed to minimize the unintended conversion during analysis.

Nonenzymatic formation of pGlu from N-terminal Glu has also been reported for recombinant mAbs [139,140,148], but this chemical change usually occurs under much harsher conditions, happens less often, and occurs at a slower rate than the formation of pGlu from Gln. This difference is likely attributable to the unfavorable hydrogen bonding propensity of Glu compared with Gln [167].

Formation of N-terminal pGlu of a protein or peptide from Gln or Glu decreases the MW by 17 Da or 18 Da, respectively. More significantly, cyclization of Gln to form pGlu causes a loss of the positively charged N-terminal primary amine, which results in an acidic shift. When separated by charge-based analytical methods, such as IEC and CIEF, mAbs with pGlu are usually the main peak, but the antibodies with Gln elute in the basic region. The identification and quantitation of pGlu-containing variants can also be done via LC/MS/MS after enzymatic digestion. Using LC coupled with electrospray ionization on a quadrupole TOF mass spectrometer (Q-TOF), Yu et al. [168] quantified the levels of pGlu at the N-terminus of the light chain of a recombinant mAb. These quantitative results were also comparable to those obtained with a more conventional peptide mapping method. Rehder et al. [110] developed an RP LC/MS method for reduced antibodies that provided efficient separation of the light chain and two variants of the heavy chain containing N-terminal Gln and pGlu. Yan et al. [141] used an RPLC–MS method to demonstrate that about 99% of the N-terminus of the heavy chain of a recombinant IgG1 contains pGlu, and about 2% of the light chain N-terminus contains pGlu [141]. Further proof of the N-terminal pGlu presence may be achieved by digestion of the mAb with

**FIGURE 10.2** Illustration of the formation of succinimide intermediate from asparagine or aspartic acid (Asp) residues and subsequent hydrolysis to isoaspartate or Asp.

pyroglutamate aminopeptidase. Samples that have been treated with this enzyme can then be analyzed using MS [148] or Edman sequencing [169].

### 10.5.2 C-Terminal Heterogeneity

***10.5.2.1 Lysine Variants*** C-terminal lysine (Lys) and arginine (Arg) residues, whose presence was expected based on gene sequence information, are often absent in proteins isolated from mammalian cell culture. This modification was first reported by Harris et al. [143,170]. This loss of Lys is presumed to be attributable to the activity of a basic carboxypeptidase in the host cells [143,171]. The degree of C-terminal Lys heterogeneity reflects the manufacturing consistency of recombinant IgGs and may be monitored for product consistency [172]. The presence or absence of C-terminal Lys residues on antibody heavy chains does not influence antigen binding [173], which is mediated by the distant CDRs. Binding to the Fcγ receptor or complement Clq is also unaffected because these interactions involve residues in the hinge-CH2 region and CH2 domains, respectively [143]. To date, the latter assumption has not been confirmed by testing the bioactivity and bioavailability *in vivo*.

Because the removal of C-terminal Lys reduces one positive charge, this charge difference can be resolved and monitored by charge based methods, such as IEF and IEC. Antibodies with different numbers of C-terminal Lys residues can also be separated by HIC [136] and RP [108]. The relative percentage of C-terminal Lys containing peptide can be determined using RP-HPLC after cyanogen bromide (CNBr) cleavage of the antibody [143]. Treatment with carboxypeptidase B (CpB) readily removes C-terminal Lys and reduces the charge heterogeneity caused by the presence of 0, 1, or 2 C-terminal Lys residues.

The removal of one C-terminal Lys residue also decreases the MW by 128 Da. Therefore, mass-based methods, such as MALDI-TOF-MS and LC–ESI-MS, can be used directly to resolve the variants with different numbers of C-terminal Lys residues on an intact mAb after N-linked glycans are enzymatically removed using PNGase F [143,171,174]. Dick et al. [171] determined that tryptic peptide mapping with LC–MS was reproducible, provides the relative percentage of Lys variants, and has significant advantages over charge-based methods.

***10.5.2.2 Amidation*** C-terminal amidation after Lys and subsequent glycine (Gly) removal is generally found in bioactive peptide hormones [175] and was observed in a monoclonal IgG1 antibody [144]. Many bioactive peptides must be amidated at their carboxy terminus to exhibit full activity. The hormones are synthesized from Gly-extended intermediates that are transformed into active amidated hormones by oxidative cleavage of the Gly N–C α bond. In higher organisms, this reaction is catalyzed by a single bifunctional enzyme, peptidylglycine α-amidating monooxygenase (PAM). Two redox-active copper atoms play a crucial role in this Gly amidation process. After being reduced by ascorbate, they catalyze the reduction of molecular oxygen for the hydroxylation of Gly-extended substrates [176]. The enzymatic mechanism requires a consensus sequence site, −XG(B), in which the amino acid to be amidated, X, is followed by Gly, G, which donates the amide group. Gly may be followed by a basic (B) amino acid [144]. In IgG1 mAbs, this consensus sequence site is present at the C-terminus of the HC amino acid sequence, SLSLS**PGK**. Studies also demonstrated that HC C-terminal amidation has no effect on Fab binding activity as measured by enzyme-linked immunosorbent assay (ELISA) and no observed differences in either effector function or antigen binding using a specific cell-based assay when main peak was compared with basic peak species [144].

Because amidation adds one positive charge to the molecule, this variant appears in the basic region of charge-based separation methods. It usually co-elutes or migrates with the C-terminal Lys-containing species. Complete removal of C-terminal Lys via CpB digestion will reveal the variants containing amidated species on the charge-based assays. The theoretical monoisotopic mass difference for the amidated peptide and the unmodified peptide ending in proline is −0.98 Da. Together with the loss of Gly residue, the mass difference between the amidated species and the nonamidated one ending in Gly is −58 Da. This mass difference can be readily resolved by reduced LC–MS. LC/MS/MS after enzymatic digestion can be used to further confirm the C-terminal peptide sequence and amidation [144].

### 10.5.3 Deamidation and Isomerization

Deamidation of Asn and isomerization of Asp are common modifications of proteins. Deamidation or isomerization proceeds via a succinimide intermediate, with the favored product being isoAsp [177,178]. Formation of atypical isoaspartyl sites via the deamidation-linked isomerization of asparaginyl peptide bonds or direct isomerization of aspartyl peptide bonds is a major contributor to spontaneous protein degradation under mild conditions. This nonenzymatic reaction reroutes the Asx–Xaa peptide bond through the β-carbonyl of asparaginyl or aspartyl residues, thereby adding an extra carbon to the polypeptide backbone. Formation of isoAsp has been implicated in protein inactivation, aggregation, degradation, and autoimmunity [118,179–182]. The succinimide intermediate is typically not stable at neutral and basic pH, but its presence has been reported for multiple mAbs [118,183].

Deamidation and isomerization occur both *in vitro* and *in vivo*. The reaction rate depends on many factors, including primary structure, three-dimensional structure, pH, temperature, ionic strength, buffer ions, and other solution properties [147,184,185]. Deamidation of Asn residues is observed most frequently at Asn–Gly and Asn–Ser sites within proteins [186], but it has recently been observed at the Asn–Asn site in the CDR region of a mAb. Deamidation can also be introduced during sample preparation for peptide mapping [170].

Although Asn is the most frequently modified residue, Gln has also been reported to undergo deamidation through the formation of a six-member ring. Gln deamidation occurs much less frequently than Asn deamidation and Asp rearrangement [187].

At neutral pH, Asn deamidation to Asp or isoAsp introduces a negative charge to antibodies and generates acidic species, which results in an earlier elution on cation exchange chromatography and an acidic shift by IEF methods [8,123,188]. Succinimide is more basic and less polar than aspartate and isoAsp and therefore elutes later on cation exchange and HIC columns [118]. A remarkable resolution between Asp- and isoAsp-containing species is possible with cation exchange chromatography given the trivial difference in charge. This separation may be caused by isomerization changing the structure in such a way that the isoAsp-containing variants present a difference in surface charge features [118].

Although charge-based methods are widely used to detect and quantitate deamidation, several methods have been used to identify deamidation sites [141,147]. Among them, tryptic peptide mapping via LC/MS/MS is used ubiquitously [8,11,147,148,188–190]. The advent of high-resolution mass spectrometers in recent years makes it possible to distinguish the parent peptide from the deamidated peptide with a mass difference of only 1 Da. Tandem MS via collision-induced dissociation (CID), which cleaves N–CO peptide bonds to produce b/y fragment ions, provides peptide sequence information and facilitates the identification of deamidation sites. Complementary to CID, electron transfer dissociation (ETD) uses low-energy electrons to irradiate the ions of interest to produce charge reduced radical ions. ETD cleaves the N–C α bonds to produce c/z fragments to allow for protein sequence analysis and amino acid side chain modification identification [191–196].

The relatively nonselective ETD fragmentation pattern makes the distinction between isoAsp and Asp residues possible using MS. Asp-N digestion has also been successfully used to distinguish aspartyl from isoaspartyl residues based on the relatively high resistance of the isoaspartyl form to Asp-N digestion [118,190,197].

Traditional N-terminal sequencing via Edman degradation is still useful not only to identify deamidation sites but also to provide information about the nature of the deamidation product, whether it is Asp, isoAsp, or succinimide. In the case of isoAsp or succinimide, no further sequence information will be observed because of the β-aspartyl residue or the five-member ring structure in the backbone, which prohibits Edman chemistry [198,199]. For the succinimide intermediate, Kwong et al. [200] determined that incubation in 2-M hydroxylamine and 0.2-M Tris buffer at a pH of 9 for 2 h at 45°C without denaturants (e.g., guanidine) will specifically cleave on the C-terminal side of succinimides without cleavage at Asn–Gly bonds. N-terminal sequence analysis can then be used to identify the internal sequence generated by cleavage of the succinimide, hence identifying the succinimide site. Care must be taken when using hydroxylamine cleavage. In earlier work done by Canova-Davis et al. [201] on the fusion protein rhIGF-I (recombinant human insulin like growth factor I), it was shown that hydroxylamine cleavage also produced hydroxamates of the Asn and Gln residues as a side product.

Enzymatic methods have been used to detect and quantitate isoAsp in peptides and proteins [146,202,203]. The enzyme protein L-isoaspartyl-*O*-methyltransferase (PIMT) catalyzes the transfer of a methyl group from *S*-adenosyl methionine (SAM) to the α-carboxyl group of an isoAsp residue and generates S-adenosyl homocysteine (SAH) as a byproduct. The methylated peptide species can spontaneously demethylate to form a succinimide intermediate and release methanol. A commercially available kit ISOQUANT from Promega (Madison, WI, USA) provides a protocol to detect the byproduct SAH using RP-HPLC. A combination of the PIMT enzymatic method and alkaline hydroxylamine cleavage can be used to selectively cleave isoAsp linkages in high yield. Location of the isoAsp linkage is then inferred by identifying the cleavage products by MS or N-terminal Edman sequencing [180].

### 10.5.4 Oxidation

Protein oxidation is a covalent modification of an amino acid that is induced by reactive oxygen species and is often a result of stress conditions or contamination [141,204]. In human antibodies, methionine residues are most susceptible to oxidation. However oxidation can also occur on cysteine, tryptophan, tyrosine, and lysine residues [150,205,206]. In IgG1, whereas Met residues at positions 255 and 431 in the Fc region are the most likely to be oxidized to methionine sulfoxide, Met residues in the Fab region were relatively stable [141,154,206]. Tryptophan oxidation was first reported by Finley et al. [152] in α-crystallin exposed to the products of a nonenzymatic, metal-catalyzed oxidation system (the Fenton reaction). The structures of oxidation products in peptides and proteins were identified. A recent study showed that oxidation of Trp 94 and deamidation of Asn 93, located in the light chain CDR of a therapeutic IgG1 mAb, correlates with loss of bioactivity upon photodegradation [207].

For therapeutic antibodies, oxidation is typically studied with thermal, chemically stressed and UV-irradiated samples [153,206,208]. Samples are either stored at an elevated temperature for extended periods of time or in the presence of oxidizing agents such as *tert*-butylhydroperoxide (tBHP), hydrogen peroxide ($H_2O_2$), or a free-radical generator, 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH) [209]. Photo irradiation with UV light also causes oxidation.

Oxidized species can be separated by a variety of chromatographic techniques, such as RP-HPLC, IEC, and HIC. Because oxidation likely occurs on the surface of the protein, it may change the overall charge distribution, resulting in subtle changes in peak shape or even resolved peaks. When separated by weak IEC, antibodies with oxidized Met residues eluted later [206]. Lam et al. [154] described the analysis of methionine oxidation in an antibody digested with papain and separated by HIC. The RP separation of oxidized antibody fragments after papain digestion was also reported [141]. Column chemistries with aromatic selectivity, such as phenyl stationary phases, were successfully used for separating tryptophan-oxidized species of antibodies. Yang et al. [151] developed an RP-HPLC method for reduced mAbs that separates the heavy chain containing oxidized tryptophan from the nonoxidized heavy chain.

Although chromatographic techniques are useful for quantifying oxidation, they do not provide site-specific information on their own. Peptide map analysis by LC/MS/MS is overwhelmingly used to identify the oxidation sites. Oxidized peptides usually elute earlier than the corresponding native peptides in a RP-HPLC peptide map. Methionine oxidation to methionine sulfoxide causes a mass shift of +16 Da. Yan et al. also observed a −64 Da fragment as the major signal in a MS/MS spectrum of the oxidized DSM(O)LISR peptides in a recombinant human monoclonal IgG1 antibody caused by the elimination of –SOH–CH3 fragment from Met side chains during MS/MS sequencing [141]. Because the formation of a sulfoxide is the main product of Met oxidation, this modification is usually observed as a discrete peak in UV peptide maps. In contrast, oxidized tryptophan has many products, including hydroxy-tryptophan (+16), kynurenine (+4), and *N*-formylkynurenine (+32) [152]. The multiple tryptophan products dilute the oxidized peptide intensity, thus making peptide mapping via UV detection alone a less sensitive choice to detect tryptophan oxidation.

### 10.5.5 Glycation

Glycation is a posttranslational chemical reaction that results in the nonenzymatic glycosylation of the N-terminal primary amine or the ε-amine group of Lys side chains by reducing sugars such as glucose and lactose. A primary amine in the protein reacts with the aldehyde group of glucose to form a labile aldimine (Schiff base) derivative of the protein. This intermediate slowly isomerizes to the more stable ketoamine adduct via the Amadori rearrangement [55,158,160,210]. Glycation of therapeutic antibodies can occur during the cell culture process [155,157] and during formulation and storage [161]. Zhang et al. [157] observed that varying levels of glycation (up to 90%) at a light chain hotspot in a mAb, and its 12 recombinant

mutants manufactured in small-scale transient CHO (Chinese hamster ovary) cell lines were related to glucose concentration in the cell culture media. Sequence alignment suggested that the coexistence of LC-Asp31 and LC-Lys49 in a mAb lead to the high rate of glycation. The substitution of either residue leads to decreased glycation. The LC-Asp31 residue acts as an internal catalyst, facilitating the Amadori rearrangement of the aldimine adduct on LC-Lys49 [157]. Harris [149] reported that glycation of Lys residues occurred in the light chain and the Fab portion of the heavy chain. A minor peak detected in a deglycosylated, humanized mAb by MS was also hypothesized to be partially caused by glycation [11]. In a separate study [76], an additional peak was observed in the mass spectrum of the light chain after papain digestion and DTT reduction. The mass of this peak is 162 Da higher than that of the light chain. Studies with different cell culture conditions, including media glucose concentrations, suggests that the +162 Da modification was most likely attributable to glycation rather than O-linked glycosylation because the levels of the +162 Da modification correlated with the concentration of glucose in the cell culture medium [76]. Andya et al. [161] reported that a spray-dried powder formulation of a recombinant humanized mAb (rhumAb) with a 300:1 lactose to antibody molar ratio stored at 30°C for 9 months was completely glycated at no less than one site, analyzed by boronate affinity chromatography. Tryptic map and MS analysis of the retained peak from boronate chromatography indicated that 16 of a total of 44 Lys residues in the primary structure were lactosylated. Although glycation is a commonly observed modification, low-level glycation on a Lys located within a heavy chain CDR of an IgG1 mAb did not significantly affect its binding potency [155].

The glycated variants can be separated and quantitated by boronate affinity chromatography using optimized shielding reagents [155]. The isolated glycated material can then be characterized by peptide mapping analysis with LC/MS/MS. Glycation masks the positive charge on the N-terminal primary amino group or on the side chain of Lys residues by converting the primary amine to a secondary amine. This conversion makes the glycated antibody slightly more acidic than the unmodified antibody. Therefore, charge-based separation techniques such as CIEF and IEC are sometimes used for measuring glycation in the absence of other acidic variants [155].

## 10.6 AGGREGATES AND PARTICULATES

Proteins commonly exhibit a concentration-dependent propensity for self-association, which often leads to the formation of aggregates and particulates (all referred as aggregates herein) that range in size from nanometers (oligomers) to microns (subvisible and visible particles). A standardized nomenclature and classification scheme that can be applied to describe all protein aggregates was proposed [211]. Five categories are described under which a given aggregate may be independently classified (Table 10.2).

Although SEC is the method of choice for quantitating soluble aggregates, the most common technique for quantitating subvisible particles between 2 and 100

**TABLE 10.2 Classifications of Particles and Aggregates [211]**

| Category | Classification |
|---|---|
| Size | Submicron |
| | 1–100 μm |
| | >100 μm |
| Reversibility | Reversible |
| | Irreversible |
| | Dissociable |
| | Nondissociable |
| | Dissociable under physiological conditions |
| Secondary and tertiary structure | Folded |
| | Partially unfolded |
| | Unfolded |
| | Amyloid |
| Covalent nodification | Cross-linked |
| | Intramolecular chemical modification |
| Morphology | Aspect ratio |
| | Surface roughness |
| | Optical properties |
| | Internal morphology |

microns is the light obscuration method [212]. This technique can determine the size and the amount of particles but cannot differentiate among the types of particles, such as protein particles, foreign material, micro bubbles, or silicone oil droplets, that can be present in protein solutions. The microflow imaging techniques can determine morphology and optical characteristics of the particles but still not identify the chemical composition. Multiple characterization and identification methods are available, such as scanning electron microscope–energy dispersive spectroscopy (SEM–EDS), micro-X-ray fluorescence, Raman microscopy (with different detection systems), microspectroscopy, microchemistry, micro-FTIR, and "rapid Identity" [212]. Such technologies can detect extremely small quantities of elements and components. The primary method for quantitating visible particles is visual inspection, a method that can be subjective and relies on adequate training of the human inspectors. Automated methods for visible particle determination are being developed.

Aggregates are a major safety concern because of their putative ability to trigger an immune response [213–215]. One ultimate goal of aggregate and particulate analysis is to ensure product consistency while minimizing the safety risk to patients. Thus, it is important to understand what is in the products and whether those aggregates present a safety issue. It is necessary to develop a particle characterization program to help address concerns during process and formulation development and ultimately, to minimize aggregate formation.

## 10.7 SUMMARY

A major task for characterization scientists in the biopharmaceutical industry is to fully characterize heterogeneous protein products in terms of their physicochemical structure; their extent of modification; and their impact on safety, efficacy, and PK. Nearly all of the major variants described in this chapter may be introduced during the manufacturing process, storage, and sample analysis [216]. With recent advances in analytical techniques and instrumentation, one can examine these variants with much greater sensitivity, resolution, accuracy, and confidence. This chapter has covered the major aspects that should be considered when characterizing a typical protein therapeutic, but there are still new variants being discovered such as the existence of trisulfide bonds [38], C-mannosylation [217], amino acid misincorporation [26,218], and N-glycosylation at nonconsensus sites [219]. Therefore, characterization scientists ought to be vigilant for new modifications.

The impact of these variants on safety, efficacy, immunogenicity, and PK cannot be generalized and must be assessed on a case-by-case basis. This usually involves additional toxicology, potency, or animal model studies. These studies can be used to link specific physicochemical attributes with biological activity and provide justification for the assignment of critical quality attributes (CQAs). The CQA knowledge is essential in understanding the critical process parameters, and designing overall control system strategies [220].

## ACKNOWLEDGMENTS

The authors would like to thank Patricia Rancatore, Boyan Zhang, Jennifer Rea, and Victor Ling for their critical review of this chapter.

# Protein and Peptide Formulation Development

SATOSHI OHTAKE and WEI WANG

## 11.1 INTRODUCTION

Commercial production of proteins was enabled following significant advancements in the development of recombinant DNA technology. However, proteins are inherently unstable and possess unique chemical and physical properties that present challenges in their purification, separation, formulation, storage, and delivery (Fig. 11.1).

The aggregation tendency of proteins is arguably the most commonly faced challenge in the development of stable protein biotherapeutics [1]. Protein aggregates have been reported to exhibit either reduced or no biological activity [2,3]; for example, direct correlation was established between the loss of recombinant factor VIII activity and the degree of aggregation [4]. Many factors affect the mechanism and rate of protein aggregation, which can be divided into two general categories: internal and external. Internal effects arise from the structure of the protein (hence the amino acid sequence) and are specific to the protein being evaluated. External factors are driven by the environment of the protein, such as temperature, solution conditions, and processing steps involved (e.g., shear stress, freeze–thaw). In situations that require drying of the protein to improve storage stability (e.g., lyophilization), solid-state condition and composition play important roles.

Because the folded state of protein is only marginally more stable than its unfolded state [5], any change to the environment can trigger degradation or inactivation. Besides aggregation, several other degradation pathways involve covalent modifications. One example is fragmentation, which involves peptide bond cleavage. Others include oxidation, deamidation, isomerization, and disulfide bond shuffling. Furthermore, proteins may undergo posttranslational modifications, including glycosylation. In addition, formulation excipients have the potential to interact with the side chain groups of a protein (e.g., Maillard

reaction) [6]. For many fill-finish operations, the physical stability of a protein can be severely impacted. Stability can be affected during freeze–thaw cycles, mixing, and filtration, which are all common process operations involved in the commercial production of protein therapeutics (see Fig. 11.1). Protein stability can be further impacted through its interaction with packaging and delivery device components.

The ideal formulation would consist of the pure, native protein by itself. For reasons mentioned earlier, it is not practical to only have the protein as the drug product (DP). This is because the protein must be purified from a complex mixture of cell debris and culture media followed by removal of any buffers or salts that are typically used for purification. Most importantly, the protein may not be stable on its own at the target concentration. For this purpose, excipients are typically included to achieve the desired stability profile. Selection of appropriate excipients and their concentrations requires a good understanding of the broad spectrum of degradation pathways affecting the protein of interest and appropriate expertise in a wide variety of analytical methods.

Regulatory guidelines are critical elements to reference during formulation development because they recommend information needed to demonstrate the safety and efficacy of the biotherapeutic. Furthermore, the results obtained allow the formulation scientist to write the appropriate pharmaceutical development section for regulatory filings. Development of commercial formulations requires a clear

understanding of the intended market. For example, information on indication, patients, method of delivery, typical dose requirement, and market distribution provides directions for the design of a successful formulation. Also, it is important to consider the competitiveness of the formulation in comparison to other products already on the market.

## 11.2 GENERAL FORMULATION DEVELOPMENT STRATEGIES

### 11.2.1 Preformulation Development

Preformulation studies are designed to probe the susceptibility of proteins to a variety of stresses. The main objectives of the preformulation study include: (1) general characterization of the product, (2) investigation of potential stability issues, (3) development of relevant analytical methods, (4) establishment of a stability profile, and (5) identification of major formulation challenges.

To predict potential stability problems within a short period of time, proteins are exposed to excessive stresses, and the resulting degradation products are analyzed. The findings from these accelerated stability studies may also be useful to predict the kinetics of degradation processes under realistic handling conditions, especially if there is a shortage of real-time results available due to time and resource constraints. The accelerated stability study is not acceptable to determine the expiry of the product. Rather, it is best used to rank order the severity of various degradation pathways observed. Not all of the degradation products are equivalent in terms of their contribution to the quality of the protein product. Thus, a qualitative assessment of each degradation product is important when weighing their significance. For example, if the degradation product compromises the safety or efficacy of the product, it should be considered more critical; certain chemical changes (e.g., deamidation) may not alter the activity of a given product, whereas other reactions (e.g., oxidation) may render the same product inactive.

The critical parameters affecting the pharmaceutical quality of a protein therapeutic are defined during the preformulation study. In many cases, formulation design is based on compromises that deal with several different problems (Fig. 11.2), as will be described in more detail later. Furthermore, the formulation will have to be optimized based on assumptions and extrapolations of results obtained during a limited time.

### 11.2.2 Formulation Development

A reliable formulation is required to support various preclinical and clinical studies. To obtain regulatory approval for the initiation of clinical trials, demonstration of safety, manufacturability, and stability of the drug is required. A sufficiently stable formulation is necessary at this stage because it is important to maintain the quality of the protein for the entire duration of preclinical studies,

**FIGURE 11.2** Pseudo first-order rate constants for isomerization (●) and deamidation (■) versus pH for a monoclonal antibody. (Adapted from Ref. [299].)

from which results will be used to support the registration of the DP with the regulatory agencies.

Different types of formulations need to be developed based on clinical needs, patient compliance, delivery method, stability of the drug, storage and distribution, and market competitiveness. Having a clear plan about what type of formulation is desired will allow the scientist to design better study plans. Typically, liquid formulations have been preferred due to their convenience of manufacture and use. However, protein drugs in liquid dosage form may not be sufficiently stable for storage and handling. Dried formulations (e.g., lyophilized) and suspension formulations (e.g., insulin zinc suspension) have been successfully prepared to overcome stability problems. In addition, specific applications and intended mode of delivery may demand the use of an alternative dosage form (e.g., spray-dried powder for pulmonary delivery).

In addition to the recommended storage condition, the effects of temperature excursion should also be tested because the quality of the DP can be severely affected. In addition, exposure to multiple freeze–thaw cycles is typically conducted as a way to determine whether the formulation can withstand unexpected freezing during distribution and storage. Likewise, sensitivity to agitation, or surface denaturation, requires evaluation to support the selection of formulation, container closure systems, and mode of shipping and handling. For formulations containing low protein concentration, special attention is required to avoid impurity-related instability (e.g., oxidation fostered by metal contaminants in excipients).

The typical starting point for formulation development is pH and buffer screen. Most chemical reactions are affected by pH (e.g., deamidation and fragmentation), as well as by the choice of buffer salt. Generally, it is preferred to select excipients that have been included in marketed products with the same route of delivery as the therapeutic under evaluation. In addition, preference is given to excipients that have

been used at similar level and frequency of dosing, history of chronic use, and on similar patient populations. Otherwise, the approval and safety of the excipients need to be examined carefully. Depending on the intended use several different pharmaceutical grades are available (e.g., USP, Ph EUR, and JP). These pharmaceutical grade materials should be considered as primary resource, however the quality provided may be insufficient. Furthermore, regulatory guidelines discourage the use of animal- or human-derived excipients.

As mentioned previously, the preference is to develop DPs in the liquid format due to ease of manufacturing; however, if sufficient stability cannot be attained, lyophilization may be considered (see Fig. 11.1). Recent improvements in device design, including dual-chamber syringes and cartridges, as well as convenient reconstitution devices, have helped the pharmaceutical industry develop lyophilized products without significant concerns surrounding patient compliance. However, it is important to note that lyophilization can present its own challenges, particularly in the design of appropriate formulations and process cycles that are economical. More detail on lyophilization is provided in Section 11.3.2.5.

Commercially viable and market competitive formulations share several common features. Most notably, the formulation should maintain the safety and efficacy profile of the protein DP throughout the handling and use period specified on the label. Shelf life needs to be adequate, under conditions to which the product will be exposed, throughout the commercial distribution system. Finally, a number of systematic studies need to be carried out to comply with regulatory requirements for registration.

### 11.2.3 Typically Observed Degradation Mechanisms

Degradation pathways for proteins can be separated into two general categories, those involving physical instability and those involving chemical instability (Fig. 11.3). Physical instability does not require covalent modification of the protein;

**FIGURE 11.3** Summary of commonly observed physical and chemical degradation mechanisms for protein pharmaceuticals.

rather, it refers to changes to its higher order structure (secondary and above). Chemical instability can be defined as any process that involves modification to the protein via bond formation or cleavage, yielding a new chemical entity. Both mechanisms are described in more detail in the following sections.

***11.2.3.1 Physical Instability*** Proteins, due to their polymeric nature and ability to adopt a higher order structure, can undergo a variety of structural changes independent of chemical modification. Typically, globular proteins have a folded (or compact) structure to minimize the exposure of hydrophobic groups to the solvent [7–9].

After the first successful expression of recombinant proteins, the formation of insoluble aggregates was observed in the host bacteria [10]. These insoluble aggregates, referred to as inclusion bodies (IBs), reduced the yield of soluble active protein and necessitated their dissociation in order to recover the bioactivity of the expressed protein [10,11]. Formation of IBs appears to be a general phenomenon and independent of the degree of overexpression. Unfortunately, a thorough understanding of the mechanism of IB formation remains elusive, which is compounded by the lack of their characterization [12,13].

In addition to IB formation during expression, several other forms of physical instability are often encountered for proteins. These include surface adsorption, denaturation, aggregation, and precipitation, some of which are interrelated. Adsorption is defined as the loss of protein caused by adherence to a surface. It is operative under all concentrations, with the loss being most significant at low concentrations. Adhesion of proteins to surfaces is a well-known phenomenon in the field of biomaterials because biocompatibility is essential for artificial limbs, organs, and contact lenses [14]. Precipitation is the macroscopic equivalent of aggregation. Protein precipitation has been known to occur for a long time, usually in conjunction with denaturation [15,16], but detailed studies have mostly been limited to the case of insulin. Recent work on insulin frosting has demonstrated that the process is accelerated by the presence of large headspace within the vial, which offers a large air–water interface at which insulin denaturation occurs [17]. Denaturation and aggregation are discussed in more detail in the next section, with emphasis on the mechanism, trigger, and formulation approaches used for stabilization.

*Denaturation* In solution, the native state of the protein is not a rigid structure. Rather, it can fluctuate to form several stable (and active) states that are difficult to detect [18]. Denaturation often refers to the alteration of the global fold of the protein, that is, a disruption of secondary and tertiary structures [16,19,20]. This process can be either reversible or irreversible and is caused by a variety of conditions, including changes in temperature, shifts in pH, and addition of organic solvents or other denaturants. The progression of protein denaturation is thought to occur in a sequential series of intermediate formation [21–23]. In fact, the denatured state is an ensemble average of several non-native protein conformations. These misfolded intermediates are often thermodynamically stable, and their rate of refolding to the native state can be quite

slow. One reason may be that the misfolded intermediate contains non-native disulfide bond(s) that require reduction for proper folding [24].

A commonly reported cause for protein denaturation is surface interaction. Adsorption of proteins to interfaces has been extensively reviewed [25,26] and thus will only be briefly discussed here. Proteins have been reported to adhere strongly to hydrophobic surfaces, but their adsorption to hydrophilic surfaces is typically weak [27]. One detrimental consequence for interfacial protein adsorption is decrease in its thermostability [28] This can be reduced, or even eliminated, by using a more hydrophilic container or through the addition of excipients. These excipients inhibit surface adsorption by competitive binding at the interface or through binding with the protein itself. A commonly used excipient for this purpose is the surfactant. When adding surfactants or other stabilizers to the formulation, the effects of the additive on the pharmacologic properties of the drug must be considered; the additives may cause leaching of the container closure components, and thus stability studies must address this possibility [29].

In addition to the container closure surface, proteins can also denature at other interfaces. Gas interface and shear forces, derived from pumping or filtration, can both lead to significant protein denaturation. Gas interface is nonpolar and can lead to denaturation via similar mechanism as described earlier for hydrophobic surfaces. The rate of denaturation at a gas–liquid interface is highly dependent on the residence time of the protein at such interface [30]. For example, the rate of protein denaturation is increased upon vigorous shaking for a prolonged period of time, resulting in the formation of soluble as well as insoluble protein aggregates [31]. Typically, the stability of a therapeutic protein in the final configuration is assessed by subjecting it to shaking for several hours, simulating the worst case level of stress caused by transportation and handling.

*Aggregation* Aggregation is the most prevalent means by which the physical stability of protein structure is compromised. Many factors lead to protein aggregation. The external environments (e.g., pH, osmolality, ionic strength) of the protein affect the structure, as will be described in more detail later. The native structure of the protein results from a delicate balance between multiple competing forces and interactions. Thus, a change in the external environment of the protein can easily disrupt such balance, leading to change in structure, which may subquently lead to aggregation. In addition to the factors listed above, temperature, exposure to light, and process-related factors (e.g., shear stress, freezing, thawing, and drying) can all contribute to destabilization. Typically, aggregation is preceded by a conformational change, which results in non-native configuration, and can proceed through multiple pathways [32,33]. It should be noted that aggregates can be soluble and their formation reversible.

In contrast to protein association, which is a reversible process that involves two or more proteins in the native state, protein aggregation typically requires the interaction of two or more denatured protein molecules. Thus, protein denaturation must occur before aggregate formation. Under typical conditions, native proteins in solution are in equilibrium with their unfolded intermediates [34], which in turn are in equilibrium with the denatured state. Several reports suggest these intermediates

to be the precursors of the aggregation process [35–37] because they expose a greater fraction of hydrophobic patches to the solvent and possess higher structural flexibility compared to the folded state [38]. In fact, simulation studies support the assertion that aggregation is accelerated by the formation of partially unfolded conformations with accessible hydrophobic areas on the protein surface [39]. Many other proteins have been reported to aggregate through similar mechanisms, including bovine serum albumin (BSA) [40], recombinant human growth hormone [41], and granulocyte-colony stimulating factor [42]. Theoretically, the completely unfolded state of a protein can form aggregates directly. The initial protein aggregates are soluble oligomers but gradually become insoluble as they exceed certain size and solubility limits. This can be present in various forms (e.g., amorphous precipitates or fibrils) and depends on the protein structure and solvent conditions. It should be noted that oligomerization is not a requirement in the process of fibril formation; for Aβ42, additives and conditions have been identified that can inhibit oligomerization without affecting fibrillization [43]. Nucleation-dependent polymerization is another mechanism that has been proposed to describe the aggregation tendency of several proteins [44,45].

Some proteins associate directly to aggregates from the native state without proceeding through an intermediate state. These associations can be driven by electrostatic, hydrophobic, or van der Waals interactions, depending on the solution condition [46]. Such association often leads to the formation of reversible aggregates, which can be considered the precursors of irreversible aggregates, or precipitates [47,48]. This process has been described as association-limited aggregation [44]. A key parameter to quantify the tendency of a protein to self-associate is the second virial coefficient, B22. Whereas a positive value indicates net repulsion, a negative value indicates net attraction. In the latter case, protein–protein interactions are favored over protein–solvent interactions, potentially leading to protein aggregation [49]. It should be noted, however, that the B22 values typically do not indicate the relative aggregation tendency of the protein [50,51]. In general, minimization of protein surface charge will likely lead to increased aggregation or particulate formation [52].

There is a narrow temperature range in which the proteins are relatively stable. Excursion from this range will destabilize the protein and potentially promote aggregation [53,54]. Typically, thermally induced protein aggregation is irreversible [55,56], although the degree of reversibility depends on the stage of aggregation process and the size of aggregates being formed [57]. In addition to the factors already mentioned, higher temperature promotes aggregation by increasing diffusion, frequency of molecular collisions, and hydrophobic interactions [38,58]. All proteins possess a unique melting or denaturation temperature ($T_m$), at which they unfold. $T_m$ is a good indication of the relative thermal stability of the protein; the higher the $T_m$, the less likely the protein will unfold. Thermally induced unfolding is often followed by aggregation due to the exposure of hydrophobic residues. There are exceptions, however. Hen egg white lysozyme with a $T_m$ of 55°C at pH 2 has been reported to resist aggregation at its $T_m$ [59]. The solution condition (e.g., salt concentration) may have an overriding effect in controlling protein aggregation.

Instability at a low temperature may facilitate the generation of unfolded intermediates, although aggregation may be retarded because of reduced hydrophobic interactions. As such, low temperature-induced protein aggregation is often reversible in contrast to aggregation induced by elevated temperature.

The solution pH dictates the type and distribution of charges on the protein surface [60,61]. These charges affect both intra- and intermolecular interactions. Due to the delicate nature of the protein structure, resulting from the balance of various interaction forces, proteins are typically stable only within a narrow pH range [62,63]. Aggregation caused by pH change can simply be an effect of altered charge–charge interactions or pH-induced protein destabilization [51,64]. At extreme pHs, proteins are heavily charged, which can lead to increased repulsive interactions. As a consequence, pH-induced protein unfolding typically does not lead to immediate aggregation [65,66]. Furthermore, changing the solution pH could potentially modify the aggregation mechanism [67]; formation of amyloid fibrils has been reported at high net charge, but particulate formation was noted under conditions of low net charge [52]. As described further below, prevention of protein aggregation needs to take into account all possible pathways. At the isoelectric point (pI) of the protein, solubility is low because of minimal protein charge–charge repulsions. Currently, no clear relationship between aggregation and pI has been established because there are examples demonstrating both positive [68,69] and negative [64,70] correlations. pH may also impact the interaction of the protein with formulation components, potentially leading to protein aggregation. In addition, pH has been reported to play a significant role in affecting the morphology of aggregates [52,59]. To maintain the pH of the solution to provide structural stability, a buffering agent is often included in the formulation. The choice of buffering agent and its concentration can have a significant impact on the aggregation behavior of proteins [62,71,72]. For example, phosphate buffers have been reported to increase aggregation in several studies [73,74].

Ionic strength (and the type of salt used to vary ionic strength) is another formulation parameter that plays a key role in affecting the aggregation tendency of a protein [75]. Increasing ionic strength often neutralizes the surface charge of proteins, thus reducing both intra- and intermolecular charge–charge interactions through enhanced electrostatic screening [76]. Its impact on aggregation depends on whether such interactions favor protein folding or association. If so, then aggregation tends to increase [77,78]. If not, aggregation will be inhibited [70,79]. Generalization is difficult because the effect of ionic strength on aggregation tendency is protein specific and can vary depending on solution conditions. Although NaCl is commonly used for adjusting ionic strength, other inorganic salts can be used and may exert a significant effect on protein aggregation, possibly through binding. Formulation approaches to inhibit or control the extent of aggregation are described in more detail later.

Protein aggregation can be induced during various processing steps (see Fig. 11.1), including fermentation and expression [80,81], unfolding and refolding [82,84], purification [85,86], freeze-thaw [87,88], shaking and shearing [89,90], pressurization [91,92], drying [93,94], preparation of protein drug delivery systems,

administration, and so on. Many impurities and contaminants that are carried with proteins during various production processes (from protein expression to manufacture of final DP) can potentially affect protein stability and aggregation. Such potential impurities include host cell proteins, enzymes, cell membrane components, residual metal ions, etc. Organic solvents can be introduced during the production of proteins and have been reported to affect their stability both positively and negatively, depending on the protein and the relative quantity or quality of the solvent [95]. The most commonly used organic solvent in protein production is glycerol, which can stabilize proteins and inhibit aggregation under certain experimental conditions [96]. Rubber stoppers are often siliconized for ease of processing during production. Trace amount of silicone has been reported to cause protein aggregation due to its hydrophobic nature; the aggregation propensity of four model proteins (concanavalin A, BSA, ribonuclease A, and lysozyme) possessing varying molecular weights and isoelectric points was found to increase significantly in the presence of 0.5% silicone oil in solution [97].

Aggregates can potentially impact the activity, half-life, and immunogenicity of the protein therapeutic [2,98,99]. As such, studies must be performed to determine the extent of aggregate formation that is acceptable for patient administration. Several reports on the relationship between aggregation and immune response have been published [100–102]. However, aggregation can at times be used advantageously, for example, to increase process yield during protein expression or purification. In these cases, aggregation is induced intentionally and is then reversed during subsequent processing. Other notable examples for desirable aggregation include crystallization and precipitation (e.g., isoelectric, salt induced). For example, the zinc hexamer of insulin is a complex of insulin and zinc, which results in the formation of insulin crystals [103]. This form of insulin has been developed for its long-acting properties because the hexamer dissociates slowly into dimers and eventually to monomers [104].

Although aggregation has been categorized under physical instability, it can also be classified under chemical degradation if it is induced through direct cross-linking. The most common cross-linking reaction is the intermolecular disulfide bond formation and exchange [62,105,106]; for example, the heat-induced aggregation of β-lactoglobulin B (β-Lg) and κ-casein [107]. Proteins not possessing any free cysteines can also undergo aggregation through a variety of mechanisms, including disulfide exchanges via β-elimination [108], oxidation [109], and the Maillard reaction [110]. It is also worth noting that multiple aggregation pathways often occur. For example, insulin can undergo aggregation via both physical (e.g., formation of soluble hexamers or insoluble fibril) and chemical (e.g., formation of soluble dimers via cyclic anhydride intermediate) processes [111–113].

***11.2.3.2 Chemical Instability*** In addition to physical instability, a variety of chemical reactions is known to occur in proteins. These reactions can involve hydrolysis, deamidation, oxidation, β-elimination, and racemization, among others. Some of these degradation pathways are described in more detail in the following sections.

*Deamidation* Deamidation is typically observed in proteins following the loss of an amine group from asparagine (Asn) and glutamine (Gln) residues, resulting in the formation of aspartic acid and glutamic acid, respectively, through a succinimide intermediate. This degradation pathway is of particular interest because this is believed to serve as a biological regulator of protein clearance mechanism *in vivo* [114]. Deamidation has been reported to have no detectable impact on the activity of some proteins (e.g., human growth hormone and interleukin-1α) [115,116] while reducing the activity of others (e.g., lysozyme and cytochrome C) [117,118]. Protein conformational changes are expected to occur upon deamidation due to the modification of surface charge distribution [7]. For example, altered forms of proteins have been reported for lysozyme [119], human growth hormone (hGH) [120], and epidermal growth factor (EGF) [121].

Deamidation of Asn and Gln residues is an acid- and base-catalyzed reaction based on elimination and hydrolysis. Whereas the acid-catalyzed reaction involves protonation of the amide leaving group, the base-catalyzed reaction involves nucleophilic attack of the amide carbonyl carbon by hydroxide or conjugate base. Deamidation of Asn residues, which occurs most often at the Asn–glycine (Gly) sequence, is reported to be accelerated under neutral to alkaline conditions [122,123]. The proposed mechanism involves the formation of a cyclic imide intermediate through nucleophilc attack of the carbonyl carbon of the Asn side-chain amide by the main-chain peptide nitrogen from the adjacent C-terminal residue [124,125]. This is reported to be the rate-determining step [126]. The cyclic imide is then base catalyzed at either one of the nitrogen–carbonyl bonds, producing a mixture of peptides in which the polypeptide backbone is connected via α-carboxyl linkage, resulting in aspartate (Asp) formation, or via β-carboxyl linkage, resulting in iso-Asp [123,127]. Thermodynamically, isopeptide formation is favored over the α-linked Asp peptide at equilibrium, typically at a 3:1 ratio [127]. Because deamidation is an acid- and base-catalyzed reaction, there is a pH at which the rate of deamidation is minimal, as has been reported for cytochrome C [128].

As the formation of the cyclic intermediate involves the participation of the neighboring amino acid, the size and physicochemical properties of the neighboring amino acid side chain are expected to play an important role in its rate of formation. Robinson and Rudd [129] reported the presence of large bulky hydrophobic groups on the N-terminal side of the amide residue to result in lower rates of deamidation; a hexapeptide with leucine (Leu) as the neighboring amino acid to Asn has been reported to be approximately 50 times slower in the rate of cyclic imide formation than that with Gly as the neighboring amino acid [126]. On the other hand, polar residues preceding Asn and Gln have been reported to result in enhanced deamidation rates. On a larger scale, the secondary and tertiary structures of the protein play a significant role in affecting the rate of Asn deamidation (e.g., an Asn that ordinarily does not deamidate in the native structure of ribonuclease was reported to deamidate in the denatured protein) [130].

Consequences of deamidation are many, including its effect on metabolic half-life, charge distribution, and conformation [131,132]. Deamidation can be a cooperative process, whereby the initial deamidation increases the rate of deamidation at

additional sites. This cooperative process may involve a structural change that moves Asn closer to residues that catalyze deamidation, promoting further flexibility and eventually leading to unfolding. If irreversible unfolding occurs, proteins are more susceptible to irreversible aggregation. On the other hand, an increase in net negative charge on the protein may lead to decrease in the rate of aggregation, caused by enhanced repulsive interactions. Very little is known about the effects of deamidation on immunogenicity because contrasting conclusions have been reported [116,133,134]. Formulation strategies to reduce or inhibit deamidation are described later.

*Oxidation* Protein oxidation (or catalyzed auto-oxidation) is one of the major chemical degradation pathways, both in solution and lyophilized formulations. This degradation pathway is complicated because any of the steps involved (initiation, propagation) can be rate limiting, and the rate-limiting step can change during the course of the reaction. This is further compounded by the variability in the location of the reactive amino acids within the protein structure; some are buried within the hydrophobic regions of the molecule and are fairly inert, while others are exposed to the solvent and are thus more reactive [135]. For example, the methionine (Met) residues in trypsin [136] and myoglobin [137] are unreactive under mild oxidation conditions, but Met in hGH [135] and transferrin [138] are partially exposed to the solvent and react at varying oxidation rates.

Several reactive amino acids (e.g., Met, cysteine [Cys], cystine, histidine, tryptophan, and tyrosine) can undergo oxidation through various mechanisms. For example, Met has been reported to be oxidized to methionine sulfoxide by atmospheric oxygen, hydrogen peroxide, and periodate, to name a few [139]. Under extremely oxidative conditions, methionine sulfone can be formed. This conversion has been associated with loss in biological activity for many peptide hormones, including parathyroid hormone [140] and corticotropin [141]. In many cases, reduction of Met sulfoxide by thiols has been reported to result in nearly full recovery of biological activity [142,143], and there are several examples for which Met oxidation does not lead to loss in protein function [144,145].

Cysteine is also easily oxidized. For a thiol group of Cys, oxidation can occur in a stepwise manner to sulfenic acid, disulfide, sulfinic acid, and sulfonic acid, depending on the reaction conditions [146]. The rate of Cys oxidation is typically accelerated at higher pH, in which the thiol is deprotonated [147], although exceptions to this rule have been reported [148,149]. In fact, pH dependence on protein oxidation may be used to distinguish between Met and Cys oxidation; whereas hydrogen peroxide–catalyzed oxidation of Cys decreases as the pH is lowered from pH 5 to 1, the rate of Met oxidation has been reported to increase slightly [150]. Cys oxidation is also strongly catalyzed by transition metal ions, especially copper.

Disulfide formation is not necessarily restricted to intramolecular reactions. If the thiol group within the protein is hindered (or only a single thiol group is present), intermolecular disulfide bonds can be formed, resulting in aggregation [151]. For example, oxidation of the well-protected Met [4] residue in the variable domain of an

IgG light chain has been reported to induce noticeable structural changes and sensitize the protein to stirring-induced aggregation [152].

Oxidizing agents that trigger the reaction include peroxides, light, free radicals, dissolved oxygen, and metal ions [153,154]. There are several reactive oxygen species, including singlet oxygen, superoxide radical, alkyl or hydrogen peroxide, hydroxyl radicals, and halide oxygen complexes. The oxidative potential is dependent on the oxidizing agent and the location of the labile residue in the protein structure.

Pharmaceutical consequences of oxidation include loss in bioactivity [33], reduced half-lives [155], and changes in antigenicity caused by conformational shifts [156]. For example, both unoxidized and oxidized Insulin B chains were reported to stimulate insulin-specific T-cell hybridomas, however xenogenic insulins did not, suggesting the importance of conformation on antigenicity [157].

*Proteolysis* Amino acids that make up the protein backbone are linked via peptide bonds. Under certain conditions, these bonds can be easily hydrolyzed to yield constituent amino acids or peptides, resulting in the disruption of protein structure. The primary impact of hydrolysis is loss in potency or activity of the protein.

It has been reported that peptide bonds of Asp residues are cleaved in dilute acid at a rate at least 100 times faster than the other peptide bonds [158]. Hydrolysis can take place at either the N- or C-terminal peptide bonds, which are adjacent to the Asp residue. The mechanism proposed by Inglis [159] involves cleavage of the N-terminal peptide bond through a six-membered ring intermediate. In a separate study, Marcus [160] has compared the lability of the Asp–Proline (Pro) bonds with that of other peptide bonds, particularly those of Asp residues. The results indicate the Asp-Pro bonds to be eight- to 20-fold more labile than other Asp-X or X-Asp peptide bonds. Peptide bonds that do not involve Asp were found to be stable to hydrolysis under similar conditions.

*Other Chemical Degradation Pathways* In addition to deamidation, oxidation, and proteolysis, several other chemical degradation pathways are possible for proteins, depending on the solvent condition and amino acid sequence. Incorrect disulfide formation results from interchange of disulfide bonds, which can lead to an altered three-dimensional structure and thus loss of catalytic activity. The reaction mechanism is different in alkaline and acidic media [161,162]; in neutral and alkaline media, the reaction is catalyzed by thiols, which in the form of thiolate ions carry out nucleophilic attack on the sulfur atom of the disulfide. Disulfide exchange can be prevented if thiol scavengers (e.g., *N*-ethylmaleimide, copper ion) are present [163].

Proteins can be sensitive to light exposure, leading to many types of light-induced degradation [164]. Recent investigations indicate ultraviolet irradiation to induce cross-linking reactions between Cys and Trp residues and photolysis of disulfide bonds, leading to new disulfide bond formation and exchange [165].

Racemization is typically considered to proceed through the removal of the α-methine hydrogen by base to form a carbanion. Racemization of Asp is

particularly interesting because the free amino acid racemizes $10^5$-fold slower than that in a protein structure, but all other amino acid residues under similar condition undergoes racemization at a two- to fourfold slower rate [166].

High temperature inactivation of proteins is often a consequence of the destruction of disulfide bonds [117,167]. Chemically, this is the result of β-elimination from the cystine residue. Besides cystine, several other amino acids (serine, threonine, phenylalanine, and lysine) have been reported to degrade under alkaline conditions [168,169]. In many cases, β-elimination is influenced by pH, temperature, and the presence of metal ions.

## 11.3 KEY CHALLENGES IN DRUG PRODUCT FORMULATION AND FILL-FINISH

### 11.3.1 Variables Affecting Protein and Peptide Stability

Formulation and fill-finish processes introduce various stresses on proteins that can cause significant degradation, as described earlier. Major stresses include temperature, pH, and shear, among others. All proteins undergo thermal unfolding when exposed to heat. The degree of thermal stability (typically analyzed and expressed as $T_m$) varies among proteins, but many proteins can denature at temperatures below their $T_m$. In fact, this is the reason why protein pharmaceuticals are sterilized by membrane filtration rather than autoclaving. Furthermore, degradative reactions described in the previous section are accelerated as the temperature is increased. Temperature can also indirectly affect the stability of the protein by modifying the pH of buffering agents as well as the solubility of oxygen in solution. pH affects both the solubility and stability of proteins, as described previously, and thus the buffering capacity of the protein-containing solution must be controlled appropriately to support all manufacturing processes involved in DP production.

Proteins may undergo aggregation or precipitation when exposed to mechanical stresses, including agitation or a high-shear environment such as pumping, filtration, mixing, and fill-finish processes [31,111,170]. Proteins also have a tendency to bind to surfaces [171]. A significant decrease in recovery has been reported in cases for which a diluted protein solution is exposed to a large surface area. Freezing, another commonly used processing step, introduces complex physical and chemical changes during which proteins can denature. As water crystallizes out of solution, the remaining solutes are concentrated along with the protein. Some solutes may crystallize, or phase separate, due to their low solubility limit, resulting in pH shift [172,173]. The surface denaturation of proteins at the ice–water interface has also been reported [174]. During thawing, the concentration gradient may not dissipate immediately, leading to protein instability. In addition, removal of water may result in alteration of protein conformation because the native structure of a protein is strongly influenced by the aqueous environment.

Extractables, leachables, contaminants, and impurities in the excipients may significantly affect protein stability. Exposure of proteins to metal ions can lead to

undesirable structural changes or precipitation [175]. Trace amount of pro-oxidants, (e.g., peroxide and hydroxyl radical) can oxidize proteins directly [33,176]. They can be introduced to the product as impurities or generated in the product by other free radical–mediated reactions of impurities. Light exposure can also result in protein degradation, which is dependent on light intensity and wave length [177].

Degradation routes at higher temperatures are typically not the same as those at lower temperatures. It has become common practice to conduct accelerated stability testing for proteins and to use the accelerated rate profiles to compare formulations and minimize degradation. This approach may provide misleading results because degradation occurring at higher temperatures may require vastly different formulation conditions for maximum stability compared to that occurring at lower storage temperatures. For example, when the stability of interleukin-1β was studied by different analytical techniques at or below 30°C, the degradation pathway was deamidation, but at or above 39°C, it was aggregation and precipitation [178]. The fact that this protein degraded by two different mechanisms precluded the prediction of shelf life using simple Arrhenius behavior. Disruption of the protein conformation can alter the spatial arrangement of charges, which in turn can affect the way in which the protein interacts with solvent molecules [179].

### 11.3.2 Compatibility with Manufacturing Process

The operations that occur after protein purification, such as freezing and thawing of the purified protein bulk, formulation (excipient addition), sterile filtration, filling, freeze drying, and inspection, are commonly referred to as formulation and fill-finish operations (see Fig. 11.1). Each step is described in detail in the following sections.

***11.3.2.1 Bulk Freeze–Thawing*** Purified proteins, also called bulk drug or drug substance (DS), are often frozen before formulation operations to facilitate storage, transportation, and handling while maintaining product quality. As such, freezing and thawing operations often constitute the first step in the formulation operation. The freezing process can be detrimental to proteins in several ways. For example, all water-soluble species in the formulation concentrate as the water phase separates (ice formation), which can lead to an enhanced rate of degradation [180,181]. Furthermore, protein-stabilizing excipients can crystallize during freezing, leaving the protein unprotected; for example, buffer components can crystallize, leading to pH shift of the unfrozen solution [172,173,182]. Proteins can denature through adsorption onto the ice surface [183] or by an decrease in temperature (cold denaturation) [184]. During the thawing process, proteins can be degraded through excessive agitation (shear and foaming) or precipitation caused by the concentration gradient.

Parameters that are critical for large-scale freeze–thaw process include: (1) temperature and rate of freeze-thaw, (2) use of agitation during thawing, (3) container selection, and (4) scale of operation. Freezing temperature dictates the thermodynamic state of the protein and its interaction with formulation excipients; if the product is frozen to a temperature below the eutectic temperature ($T_e$) of the crystalline additive, it is no longer available for proper interaction. Typically, the

target freezing temperature range is determined based on thermal analysis data obtained via differential scanning calorimetry (DSC), which provides information on various phase transitions for the components present in the formulation. Temperature–time profiles can be obtained experimentally by freezing the bulk in the selected container or freezer and positioning temperature recorders at various locations within the solution. Proteins have an optimum freezing rate; very high rates can be detrimental to the stability of proteins due to the creation of an excessively large ice surface area. In contrast, slow rates expose proteins to freezing-induced conditions for a prolonged period of time. For example, increased protein aggregation and decreased activity have been reported for liquid nitrogen–based freezing systems [87,183]. Fast freezing can also trap air that could be released during thawing and may cause protein denaturation at the air–liquid interface [185,186]. Controlled rate technologies, such as Celsius-Paks or CryoVessels, can achieve faster freeze–thaw rates by using a combination of small path length and increased flux for heat transfer [187]. Freezing time is another critical parameter controlled to ensure completion of the freezing process. Placebo experiments at the maximum intended bulk load can provide information about the longest freezing times and slowest freezing rates. After obtaining freeze–thaw profiles at full scale, the impact of the rate on protein integrity is tested by subjecting the protein to the worst-case freeze–thaw profile. It should be mentioned that concentrated protein solutions are often more resistant to freezing-induced protein aggregation [187,188]. The increased stability at high protein concentrations during freezing is likely attributable to one or more of the following factors: (1) limited area of ice–water interface for denaturation, (2) self-stabilization of proteins [47,183], and (3) conversion of monomers to active and more stable dimers or multimers [189,190].

Thawing temperature dictates the time required for the process and the rate of liquefaction of the freeze-concentrated protein. To expedite the thawing process, it is typically advisable to select the thawing temperature reasonably high, based on available stability data. Thawing time is determined by performing a full-scale experiment with the protein or placebo (if protein supply is limited). Completion is confirmed by visually ensuring that there are no residual ice crystals in solution. Similar to freezing rates, the faster the thawing rates, the better the product stability (although up to an optimum level). Slow thawing rates can result in ice recrystallization, with small ice crystals growing into larger ones; proteins may denature at the ice–liquid interface and lose their activity [191,192]. Cryoconcentration created during freezing can further harm the protein during thawing. The thawing method may or may not involve some type of agitation. Agitation helps maintain a uniform temperature, if the thawing temperature is different from the storage temperature, and minimize recrystallization and cryoconcentration-related effects. Very high thawing rates may result in foaming and thus to shear-induced and surface-mediated protein denaturation.

All of the factors described are linked to the scale of operation, material of construction, and configuration of the container. The container size is often dictated by the volume of the production batch and the frequency of production. Product stability and the batch volume typically play a role in the selection of an appropriate

container configuration. If material availability is a concern, preliminary experiments can be performed with a commercially available scale-down tool (e.g., cryo-wedges). Cryo-wedges are designed to subject the protein at small scales (~0.5 l) to the same freeze–thaw profile experienced at a larger scale. Some other considerations for container selection include its ease of use and transportation, sterilization method, chemical resistance, tamper evidence, and compendia requirements. The selected container is validated prior to experimentation, and container closure integrity should be ensured for the proposed freeze–thaw process. For a review of large-scale protein freeze–thaw operation, readers are referred to publications by Wisniewski [193,194] and Wisniewski and Wu [195].

***11.3.2.2 Formulation*** The purified form of the protein is usually stored in buffer, which typically does not contain all of the ingredients required in the final formulation. Rather, if the DS is frozen, cryoprotectants are present, which may or may not be required in the final DP formulation. Furthermore, the protein concentration at the end of purification may be different from that required for DP. This is because it is operationally more favorable to store the DS at a higher concentration than that intended for the final formulation. Thus, after thawing of the frozen DS, its concentration is adjusted, and the desired excipients are added (and extraneous excipients are removed). In other cases, buffer exchange may be required between the DS and DP, typically using an ultrafiltration (UF) or diafiltration (DF) step. Although this sounds simple, the labile nature of proteins and the scale of operation involved offer many possibilities for protein degradation. Exposure of proteins to air–liquid interfaces during processing (e.g., pumping, mixing) and their interactions with large surfaces of tanks and tubing material over extended periods of time can lead to unfolding or adsorption to surfaces. On the other hand, insufficient mixing during the addition of excipients could alter product quality (solution inhomogeneity), resulting in the final DP being out of specifications. In certain applications, a concentration step may be required if the DP is to be formulated at a higher concentration than the DS. High product concentration and viscosity could pose further challenges for membrane filtration during the concentration step. Thus, careful consideration must be given to each unit operation to ensure that protein integrity and activity are maintained.

The formulation process should be carefully designed by taking into consideration all possible concentrations of the purified and formulated bulk, as well as process consistency and ease of operation at multiple manufacturing sites. The constituent buffer should be carefully selected so that the operation is simple yet robust, with appropriate tolerances in place. Buffer tolerances are established such that the process is practically feasible while yielding a product that is within established specifications for purity, potency, safety, and efficacy.

Various excipients are included in the formulation to protect the protein against multiple degradation pathways. Common attributes of desirable excipients are aqueous solubility, non-toxicity, non-reactivity, rapid clearance from the body, and lack of immunogenicity. In addition, the excipients should be capable of stabilizing the native conformation of the protein during processing, storage, and

administration to the patient. Some of the simplest and most effective are salts [196–198] and polyalcohol compounds, such as glycerol and sugars [199–201]. The purity of excipients is another key factor affecting product quality [202]. Certain impurities in the raw materials can trigger degradation reactions; for example, peroxides in polysorbate can lead to protein oxidation, and trace amounts of metals can lead to aggregation [203,204]. Use of animal-derived excipients may carry the risk of causing transmissible spongiform encephalopathies, thus requiring careful evaluation. The choice of raw material suppliers is critical. The order of addition of excipients can also impact product quality; in some cases, interim interactions between excipients may occur at concentrations higher than their equilibrium concentration in the post-mixed, formulated bulk. For example, addition of polysorbate is often performed following the UF/DF step to minimize its loss caused by interaction with the membrane component. In addition, surfactants could be adsorbed onto surfaces (i.e., tubing and tanks), thus resulting in lowered surfactant concentration in the formulated bulk. Leachables and extractables from various contact surfaces also have the potential to affect product integrity.

Small-scale characterization studies should be conducted to evaluate protein stability under appropriate formulation conditions. Buffers should be characterized to establish tolerances around excipient concentrations, pH, acid–base volumes required, conductivity, and osmolality. Hold time studies using the worst-case scenario for surface area exposed per unit volume should be designed to examine the impact of different contact materials on protein stability. Temperature excursions should also be evaluated through hold time studies. Characterization of the mixing process should include both product homogeneity testing and impact of mixing shear on product quality. Also, compatibility of the protein with product-contacting surfaces (e.g., pumps and tubing) should be examined. These findings can then be verified with fewer runs at commercial scale to determine their impact on DP quality.

Formulation approaches to counteract several degradation mechanisms described in the previous section will now be reviewed. Focus will be on denaturation, aggregation, deamidation, and oxidation.

*Formulation Approaches for Countering Denaturation and Aggregation* A protein DP may contain a specified acceptable level of aggregates not only after initial product release but also during the shelf life of the product. The aggregation rate of the protein needs to be estimated and controlled during product development so that the limit will not be exceeded during manufacture and storage. Because the solvent environment dictates the ability of the protein to maintain its native state and resist denaturation from various stresses, several excipients and their combinations are empirically tested. One popular mechanism that describes the efficacy of additives, or co-solvents, to inhibit protein unfolding is preferential hydration. Excipients are referred to as co-solvents because they affect the solvation of the protein. Co-solvents include salts, sugars, buffers, and amino acids. A co-solvent is excluded from the protein surface as a result of either inert steric exclusion effects (e.g., increase in the surface tension of water) or chemical incompatibility with the protein surface (e.g., charge repulsion), thus leaving

the protein to be hydrated with water [196,205–208]. In contrast, co-solvent binding describes mechanism of protein destabilization through binding of co-solvents, which can be either non-specific or specific [205]. Several studies have demonstrated that many denaturants cause global changes to protein conformation rather than bind to specific sites [209,210]. The classification of co-solvents into these two categories is often difficult because several additional factors influence their behavior [211]. For example, although surfactants are generally considered co-solvents, they display unique features that are not observed for other co-solvents [212]. Other mechanisms are also operable, such as an increased rate of protein folding [213,214], a reduction of solvent accessibility and conformational mobility [215], and an increase in solvent viscosity [216].

Based on the information gathered during preformulation studies, as described earlier, the aggregation tendency of the protein candidate can be quickly evaluated at various pH, ionic strengths, and storage temperatures. The assessment of formulation efficacy can be conducted by the use of appropriate analytical techniques, including size exclusion high-performance liquid chromatography (SE-HPLC), isoelectric capillary eletrophoresis (iCE), light scattering, and so on. If a high dose is projected for clinical use by subcutaneous (SC) injection, information on the solubility and viscosity of the protein candidate is required. Four major parameters are typically examined during formulation development; pH, buffering agent, salt, and stabilizers (if required). A wide pH range needs to be examined because the relationship between protein aggregation and pH is often complex and difficult to predict. Several types of relationships have been reported, including well-shaped [178,217], bell-shaped [76,218], sigmoidal [219], and linear [220] relationships.

Next step in formulation development is the identification of an optimum ionic strength to minimize protein aggregation, which can be highly protein dependent [5]; it should be noted that the salt type can have a significant impact on protein aggregation [75]. Although many buffering agents are available for pH adjustment, the aggregation behavior of proteins can vary drastically in different buffer systems and concentrations [62,71,221]. Many stabilizers, including sugars, polyols, amino acids, amines, salts, polymers, and surfactants, can reduce protein aggregation [1,222,223].

Sugars and polyols can help maintain the correct conformation of proteins, serving as co-solvents [224]; however, they do not appear to work equally well on all stages of the aggregation process [225]. Surfactants can be generally divided into two classes, non-ionic and ionic. Both classes have been demonstrated to affect protein aggregation induced by different stresses. The major rationale for using surfactants in protein formulations is their ability to bind to hydrophobic interfaces that are potential denaturation sites [226,227]. Non-ionic surfactants are a well-known class of excipients, often used to prevent or inhibit protein aggregation [212] and adsorption to surfaces [228,229], as well as to hinder denaturation [230,231]. A commonly used type of non-ionic surfactant for this purpose is polysorbate (Tween) [212]. The reported effects of non-ionic surfactants on protein aggregation have not been consistent among different proteins because their effects are multifaceted [49,178,232,233]. Ionic surfactants, or surfactant-like compounds, have been

reported to affect protein aggregation more intensely than non-ionic surfactants. This is due to their strength of protein binding, facilitated by their interaction with both polar and nonpolar groups [82,234,235]. In several cases, however, ionic surfactants have been reported to induce protein aggregation [236]. The presence of other co-solvents may alter the physical characteristics of surfactants. For example, addition of co-solvents that cause preferential hydration of the protein (e.g., sugars) may also cause hydration of the surfactant, resulting in phase separation. Some protein DPs need to be manufactured with preservatives to accommodate multiple administrations. Yet these preservatives may not be compatible with the protein of interest. Preservatives often contain a hydrophobic component, which can bind to proteins, as discussed earlier for surfactants.

Several types of small charged additives have been reported to affect the aggregation tendency of proteins [237]. This may be influenced by the modification of solution ionic strength or through specific interactions with proteins [74,238]. Some positively charged amino acids (histidine [239], lysine [240], and arginine [241]) are particularly effective in inhibiting protein aggregation. The mechanism for the protective effect of arginine has been studied in several laboratories. This was thought to be attributable to the ability of arginine to solubilize proteins through the weakening of protein–protein interactions rather than a protein stabilization effect [242]. Additional evidence suggests that arginine deters aggregation by slowing protein–protein association reactions through preferential exclusion [243]. Metal ions play a critical role in maintaining the correct conformations for several proteins [244,245]. In many cases, metal ions can facilitate aggregation of proteins. The pro-aggregation effects are generally mediated through binding to proteins [90,246]. Binding can result in small changes in the tertiary structure of proteins, leading to the formation of aggregation-competent conformers. The effect of metal ions is often concentration dependent [247]. Metal ions also influence the kinetics of protein aggregation and the properties of aggregates. Polymers have been extensively used with proteins. They may inhibit protein aggregation through: (1) surface activity, (2) preferential exclusion, (3) weak binding, (4) steric hindrance of protein–protein interactions, and (5) increased viscosity, limiting protein structural movement [66,248]. It seems that the overall effect is a balance between protein binding and macromolecular crowding effect. Among these interaction forces, hydrophobic interactions appear to be more effective in controlling protein aggregation than charge effects [249].

Many studies have been conducted to evaluate the effect of protein concentration on aggregation. Because of the existence of several aggregation pathways (e.g., partial unfolding induced, simple native association-initiated aggregation), increasing protein concentration could potentially result in a number of effects, including increased aggregation caused by a greater chance of association [46,48], decreased aggregation caused by a crowding effect [98,250,251], and precipitation [81,252].

If proteins demonstrate a high tendency to aggregate in the liquid state and no effective formulation approaches can be found, preparation of a dried dosage form may be a viable alternative. The commonly used method for preparing a solid product is lyophilization, as will be discussed later.

*Formulation Approaches for Countering Deamidation* The main strategy to reduce deamidation in proteins involves optimization of solution conditions (excipients, pH, ionic strength, and temperature). Knowledge of the deamidation mechanism can help in the search for an optimum pH. Furthermore, the anion present in the buffer solution have been reported to play a significant role in impacting deamidation rates [253]. These effects are described in more detail below. Moreover, because the degradation pathways can be temperature dependent, data from accelerated stability studies may not always be extrapolated to real-time studies.

The mechanism of deamidation often dictates the formulation pH. If deamidation proceeds by a general acid–base-catalyzed mechanism, then it may be possible to formulate at an optimum pH, at which both rates are minimized. For example, deamidation that proceeds through the cyclic imide intermediate is base catalyzed, and thus lowering the pH should greatly reduce the rate of deamidation.

It is widely known that deamidation is markedly dependent on the type of buffer anion used [254]. Gilbert et al. [253] investigated the deamidation of Gln to Glu in the presence of different sodium buffer salts at pH 8 and 37°C. The rates of deamidation were high in phosphate, arsenate, and bicarbonate. In contrast, there was no observed rate enhancement by sulfate, nitrate, acetate, chloride, or pyruvate anions. The deamidation rate decreased upon the addition of organic solvents, with the reduction in rate constant being directly proportional to the concentration (and choice) of organic solvent. For example, solvents such as ethanol reduced the rate of deamidation while polyethylene glycols (PEG 4000 and 8000) demonstrated only a slight retardation in deamidation rate for several peptides as a function of PEG concentration [253]. For the hexapeptide Val-Thr-Pro-Asn-Gly-Ala, the main reported effect of co-solvent addition has been the decrease in the dielectric constant of solution [255]. More specifically, the decreased deamidation rate is attributable to the destabilization of the deprotonated peptide bond nitrogen anion in solvents with low dielectric constants. The effect of ionic strength on the rate of deamidation was studied using the glutaminyl pentapeptides (Gly-Leu-Gln-Ala-Gly and Gly-Arg-Gln-Ala-Gly) [256] and the asparaginyl pentapeptide (Gly-Arg-Asn-Arg-Gly) [257]. These studies demonstrated deamidation to proceed at a faster rate with higher ionic strength, which supports the previous work with Gln [253].

*Formulation Approaches for Countering Oxidation* Protein oxidation in solution is highly dependent on the temperature, dissolved oxygen, light, and excipients used. The addition of polysorbate 80 to lyophilized interleukin-2 formulations has been reported to stabilize the product nominally but to increase the amount of protein oxidation [258]. Oxidation was caused by the high peroxide content in polysorbate 80 remaining after purification and bleaching. Peroxide is known to increase upon storage, particularly at higher temperatures [259,260]. There are three classes of antioxidants. The typical antioxidants are phenolic compounds, including butylated hydroxytoluene, butylated hydroxyanisole, propyl gallate, and vitamin E. Reducing agents form the second class of antioxidants, which includes ascorbic acid, sodium sulfite, thioglycerol, and thioglycolic acid. These act as oxygen scavengers in a closed system, wherein they oxidize preferentially over the protein. The third class of antioxidants includes

chelating agents such as EDTA (ethylenediaminetetraacetic acid), citric acid, and thioglycolic acid. These antioxidants act by removing trace metal ions that play a major role in initiating auto-oxidation reactions.

Typically, the first set of strategies for minimizing protein oxidation is to refrigerate, protect from light, remove oxygen, and adjust the pH. Because trace contaminants present in various excipients can also impact oxidation, excipient screening and an effective selection process based on drug stability data are critical. Replacement of headspace oxygen in both solution and dry-powder formulations may also be required. When oxidation is light induced, protection of protein solutions from light may be required.

***11.3.2.3 Filtration*** Following formulation, the active product is sterile filtered (using a 0.22-μm pore size membrane) to ensure that the product is free of bioburden. Polyvinylidene fluoride (PVDF) membranes are commonly used for this purpose. Product compatibility with the filter membrane material is tested during validation studies prior to the use of filters at a commercial manufacturing site. Filter size recommendation is critical and can be product specific. Too small a filter could prolong the filtration time, but too large a filter could result in large hold-up volume, which in turn leads to greater product loss. Other critical parameters that require careful consideration include: (1) allowable pressure drop across the filter, (2) duration over which the filtered product can be held to maintain product sterility, (3) temperature of the operation, and (4) the mode of liquid transfer during filtration. All filters are integrity tested before and after use, per established procedures.

An additional in-line filtration step might be incorporated before filling. Dual filtration may also be used for risk mitigation in the scenario of filter failure. Thus, the protein solution may be exposed to multiple filtration steps prior to filling as a final dosage form in the selected container. It is therefore important to evaluate the impact of filtration process on product quality. Sterile filtration at a high trans-membrane pressure could stress the protein. The protein can also bind selectively to the membrane, resulting in either misfolding or protein loss. Similarly, other formulation components (e.g., surfactants that are added as stabilizers) may get adsorbed onto the membrane surface. This causes the surfactant concentration in the solution to decrease below the target value. Thus, the order of addition is a key consideration.

***11.3.2.4 Fill*** After the DS has been formulated and sterile filtered, it is filled into primary DP containers, which are typically vials or syringes for prefilled injectables. All of the container closure surfaces are often treated with different coatings to minimize protein binding and facilitate their processing (e.g., insertion of stoppers into vials). During this step, the DP not only comes into contact with the primary container but also with the various components such as stoppers, plungers, and so on. All of these components are subjected to sterilization processes separately and brought together under aseptic processing conditions [261]. The container closure system and the environment of the fill chamber are qualified to be of the highest standards needed to ensure product quality and sterility.

Prior to fill, the vials are washed, depyrogenated, and then cooled to room temperature. Stoppers are generally washed, siliconized, and sterilized, although pre-washed and pre-siliconized stoppers are commercially available. Some of the critical attributes include: (1) the type of silicone used, (2) the extent of siliconization, (3) the stopper composition, (4) the residual moisture of the stoppers, and (5) the moisture permissibility of stoppers. Rubber stoppers are lubricated with silicone to ensure appropriate closure fitting into the vial neck, and adequate siliconization ensures proper machinability of the stoppers on the fill equipment. Silicone is considered relatively inert, and its concentration in DP containers is significantly low to ensure no risk with respect to biological incompatibility. However, interaction between proteins and silicone oil has been reported to induce protein aggregation or product inactivation [97]. Knowledge of the residual moisture content of stoppers and the moisture-vapor transmissibility are critical for lyophilized formulations, for which moisture transfer from and through the stopper to the product is a concern [262]. Also, the possibility of any deleterious interactions between the product and any leachables from the vials or stoppers requires investigation.

Besides silicone oil, other constituents of the primary container have the potential to contribute to leachables and extractables at a concentration that can affect protein stability and activity [263,264]. Leachables are contaminants that have migrated from packaging components (e.g., plastic bottles, glass vials, prefilled syringes, rubber stoppers) or manufacturing equipment (e.g., tanks, tubing) into the product during DP processing through prolonged exposure. Extractables refer to species that are released from the material of construction of the contacting surface caused by prolonged interaction with the product under specific solvent and temperature exposure conditions. In addition to toxicologic concerns, these chemicals can also impact protein stability.

Filling of liquid protein pharmaceuticals is performed in a clean room of appropriate classification (class 100). Most manufacturing facilities use automatic fill machines with multiple needles. Studies are conducted with the product to determine the fill-accuracy capabilities of the equipment and the amount of unrecoverable product (i.e., holdup volume) from vials and disposable syringes. Based on these values, a target fill weight and tolerances around that value are established. Automatic fill machines typically have the capability to periodically test fill weights online. The filling device's materials of construction (for product contact) must be compatible with the protein. In addition, the shape and height of the filling nozzle, as well as the fill speed, could contribute to foaming in vials that could possibly result in exposing the hydrophobic residues of the protein to air and initiate protein aggregation at the air–water interface. Although it is necessary to keep the filling speed as high as practically achievable to maintain high throughput, very high filling speeds can lead to foaming, and subsequently to protein denaturation [265]. The maximum time the product can be held at room temperature during fill is based on product stability data, which are recorded for ensuring product stability. For some liquid-dose products, the vial headspace is overlayed with nitrogen gas to reduce potential for product oxidation by headspace oxygen

[266]. Light exposure during fill and post-fill processes may also result in protein degradation for certain products.

***11.3.2.5 Lyophilization*** There are two major product forms for commercial protein pharmaceuticals: liquid and freeze-dried solid. Due to their ease of processing, the low cost of production, and the convenience of administration, liquid protein products are typically preferred unless aggregation or other forms of instability is difficult to control adequately. If the product shelf life is insufficient in liquid dosage form, freeze-dried formulation is a viable alternative. Freeze-drying, or lyophilization, is the process by which the water content of the product is reduced by freezing followed by removal through sublimation under vacuum. Although a freeze-dried protein formulation generally offers enhanced protection against protein modification, the freeze-drying process itself could cause significant protein degradation.

Freeze-drying improves product stability by: (1) maintaining the protein in an amorphous phase with its stabilizers, (2) immobilizing the protein in a glassy phase below the glass transition temperature ($T'_g$) of the formulation, and (3) reducing the residual water content to a low, desirable value. The lyophilization process primarily consists of three stages. The first stage involves freezing the product and creating a frozen matrix suitable for drying. This step impacts the drying characteristics in the subsequent two stages. The second stage is primary drying, which involves the removal of ice by sublimation through reduction in chamber pressure while maintaining the product temperature at a low, desirable level. The third stage in the process is secondary drying, during which the water content is further reduced until the target level is reached. Some of the crystalline additives, such as mannitol and glycine, may not crystallize completely during freezing. These excipients have low $T'_g$ values and, if not crystallized fully, they contribute to the overall $T'_g$ of the formulation (i.e., $T'_g$ depression). Low $T'_g$ necessitates drying at lower temperatures, which prolongs the cycle time. This can be avoided through the use of pre-sublimation annealing, which requires holding the system for some time at a temperature between the ice melt and $T'_g$ of the freeze concentrate [267]. There are two main purposes behind this step: (1) to crystallize bulking agents such as glycine and mannitol and (2) to allow larger ice crystals to grow (Ostwald ripening). There are two physical phenomena that should be avoided during a lyophilization process: collapse and meltback.

Collapse is described as the loss of microscopic and macroscopic structure of the freeze-dried product. Collapse is typically observed if the product temperature exceeds a characteristic temperature called the collapse temperature ($T_c$). When this occurs, the matrix collapses under its own weight. In addition to losing pharmaceutical elegance, collapsed product may lead to increased residual water content, uneven distribution of moisture, longer reconstitution times, and possible conformational changes of the protein. $T_c$ is unique to a given formulation and correlates well with the $T'_g$ of the formulation; the $T_c$ is usually slightly higher than the $T'_g$. Primary-to-secondary drying transition is critical because a premature transition to a higher shelf temperature can lead to product collapse; as the water

is removed, $T'_g$ of the amorphous phase increases, but caution must be taken to implement a slow rate of increase in temperature, so as to always stay below the glass transition temperature of the amorphous phase [188].

Most formulations contain crystalline components such as mannitol or glycine as bulking agents. Eutectic melting of these crystalline components leads to meltback. To avoid meltback, the product needs to be held below the eutectic melting temperature ($T_e$) of the crystalline components contained in the formulation. $T_e$ is the crystalline analogue of $T'_g$. Because the $T_e$'s of commonly used bulking agents are typically higher than the $T'_g$ of the amorphous phase, meltback can be prevented by keeping the product below the $T'_g$ of the formulation.

For freeze-dried products, the formulation and the lyophilization process are intricately interrelated. As mentioned earlier, to maintain product stability, the product temperature must be maintained below $T'_g$ both during drying and storage. Therefore, a formulation with a higher $T'_g$ allows drying at a higher temperature compared to that with a lower $T'_g$, which subsequently expedites the freeze-drying time. Typically, the $T'_g$ of a given formulation is determined experimentally before a lyophilization cycle is developed. This can be done using several techniques, including DSC. $T_c$ can be determined using a freeze-drying microscope by freezing the material and raising the temperature to observe the onset of collapse [268].
